ABSTRACT

This thesis uses autoencoders to explore the possibility of reducing the length of the Autism Diagnostic Observation Schedule (ADOS), which is a series of tests and observations used to diagnose autism spectrum disorders in children, adolescents, and adults of different developmental levels. The length of the ADOS, directly and indirectly, causes barriers to its access for many individuals, which means that individuals who need testing are unable to get it. Reducing the length of the ADOS without significantly sacrificing its accuracy would increase its accessibility. The autoencoders used in this thesis have specific connections between layers that mimic the sectional structure of the original ADOS. Autoencoders reduce the length of the ADOS by conducting its dimensionality through combining original variables into new variables. By examining the weights of variables entering the reduced diagnostic, this thesis explores which variables are prioritized and deprioritized by the autoencoder. These information yields insights as to which variables, and underlying concepts, should prioritize in a shorter ADOS. After training, all autoencoders used were able to reduce dimensionality with minimal accuracy losses. Examination of weights yielded many keen insights as to which ADOS variables are the least important to their modules and can thus be eliminated or deprioritized in a reduced diagnostic. In particular, the observation of self-injurious behavior was declared entirely unnecessary in the first three modules of the ADOS, a finding that corroborates

other recent experimental results in the domain. This observation suggests that the solutions converged upon by the model have real-world significance.

ACKNOWLEDGEMENTS

I dedicate my thanks to my beloved parents for their encouragement and believing in me. Many thanks to my motivational source my sister Wid Daghustani for being such an inspiration to me. My thanks to all my friends who helped me pass all the obstacles in my master's degree journey. Thanks to everyone I meet through my studying years for his or her help. I am also grateful to Mr. Mohammad Al-Hijjawi for providing me Nvidia GPU Hardware. My appreciations to my adviser Dr. Voigt for her precious supervision and suggestions during the thesis progress. Moreover, thanks to the committee members Dr. Georgiou and Dr. Sun for their cooperation.

CHAPTER ONE

INTRODUCTION

1.1 Introduction

Autism spectrum disorders (ASD) can pose tremendous developmental challenges to children who have them. When parents suspect that their child's neurological development is abnormal, it is essential for them to have their child examined and assessed by experts to verify if an autism spectrum disorder causes their troubles. Unfortunately, the autism diagnostic process is often cumbersome and costly, and many parents faced with significant barriers to its access. Many of these obstacles, directly and indirectly, result from the length of the autism diagnostic process. If the process could shorten without decreasing its effectiveness, many parents and their children could greatly benefit from the erosion of barriers to accessing autism diagnostic services.

Autism spectrum disorders (ASD) are a group of complex neurological conditions of brain development. These disabilities are characterized by weakness of social interaction and communication, repetitive and stereotypic behaviors, reorganized in children during the first years [1]. The symptoms of ASD are apparent in children before three years of age, but in a rare situation, it can diagnosed at even earlier stages.

According to a US government survey of American parents, in the United States, for every 45 children, at least one is diagnosed with ASD [2]. This number

is higher than the Center for Disease Control and Prevention's (CDC) estimation, which claims that one in 68 children is diagnosed with ASD [3]. The incidence rate of autism worldwide is approximately 20 per 10,000 children, and it is four times greater in male children than in female children [4].

Autism diagnosis is a process executed by specialists to verify the existence of autism, identify its causes, and to propose appropriate therapeutic intervention programs. Autism is difficult to diagnose, and the process of diagnosis is an ongoing research challenge for specialists in the field. The current standard for autism diagnosis is the Autism Diagnostic Observation Schedule (ADOS), which is a series of tests and observations administered to children, adolescents, and adults of different stages of development. The length and complexity of the ADOS logistically limits the number of individuals that can be tested for autism. If the ADOS was shorter and less complex, evidence exists to suggest that a more substantial amount of individuals could access and afford autism diagnosis services.

1.2 Thesis Scope

his thesis uses autoencoders to test if all four modules of the Autism Diagnostic Observation Schedule can be reduced in dimensionality, and to examine which variables are prioritized and deprioritized in the dimensionality reduction process. The impact of original ADOS variables in the reduced

diagnostic is reviewed, and all insights gained from this process are catalogued and explored.

1.3 Purpose

The purpose of this thesis is to create an algorithm that reduces the length of the Autism Diagnostic Observation Schedule by lowering its dimensionality without significantly sacrificing its accuracy. The algorithm is designed to incorporate the sectional structure of the ADOS. When reducing dimensionality, the algorithm prioritizes and de-prioritizes different variables. Examining this information will yield insights regarding the ideal conceptual focus of potentially reduced versions of the ADOS.

The ADOS is currently a long and cumbersome test to administer, which is problematic from an access standpoint. There is plenty of evidence that indicates that autism is under-diagnosed in developing countries. Part of the problem is that there are too many barriers to administering the test. According to a paper covering the hurdles of implementing the test in Jamaica, high administration costs and long waiting lists prevent many children from being tested for autism [5]. The high administration cost and long waiting lists can likely be at least partially attributed to the length of the test. More extended tests reduce the number of tests that can be administered in one day, which undoubtedly exacerbates long waiting lists. Likewise, the length and complexity of the test

drive up administration costs [6]. Finding a way to reduce the test without sacrificing its accuracy could allow for a newer version of the ADOS to be accessed by more significant numbers of potential patients worldwide. Any project that assists in this endeavor is a worthwhile task. In the United States, a full-length neuropsychological evaluation of the potential for autism spectrum disorder within a child can cost between $1,200 to $2,500 and take up to five hours. For a bare bones autism diagnostic process, without any interaction with parents or detailed feedback, the price can range from $500 to $800, and can take up to 2 hours. The price of these procedures depends upon the length and amount of labor required from highly-compensated specialists in the field [7].

1.4 Approach

This thesis employs an autoencoder with connections that mirror the sectional structure of each ADOS module. The extent which each variable in the input influenced the reduced-length diagnostic is assessed and their relative impacts are ranked. This information might yield insights as to which aspects of the ADOS are the most and least important. Furthermore, this thesis aims to provide as much useful information as possible to psychologists designing the next version of the ADOS. All unusual patterns and trends from the results of the autoencoders are cataloged. It is possible that this information could shed light

on the way that different tests within the diagnostic could be fused for the sake of efficiency.

CHAPTER TWO

BACKGROUND

2.1 Introduction

This section is an overview of the field of machine learning and the background mathematical and algorithmic techniques needed to comprehend the research methods used in this thesis.

2.2 Machine Learning

Machine learning is artificial intelligence research branch that involves a combination of statistics, mathematics, and programming. Machine learning algorithms train a computer to correctly execute a task on its own, without explicit programming. There are three types of machine learning tasks: supervised learning, unsupervised learning, and reinforcement learning.

2.3 Supervised Learning

Supervised learning involves training a machine learning algorithm to find a target function that reliably maps an input (or set of inputs) to an output (or set of outputs). The algorithm is trained with a dataset that contains the correct outputs. This dataset is typically referred to as the training set. During training, the algorithm increases the accuracy of its target function iteratively. Once the algorithm trained, the efficiency of the algorithm is tested on a new dataset called

the test set. There are two common types of supervised learning problems: classification and regression.

2.3.1 Classification

In a classification problem, an algorithm attempts to map an input to a categorical variable. The goal of classification is to figure out which category an input falls into, given a set of options. An algorithm is judged by the accuracy by which it can correctly predict which group an input should place too.

2.3.2 Regression

Regression tasks involve mapping an input to a continuous variable. In this case, the algorithm attempts to predict the correct output value. The accuracy of the algorithm is judged by the average error between the network's output predictions and the correct values.

2.4 Regularization

Regularization, in machine learning, refers to a process by which overfitting can be avoided. Overfitting occurs when a model adapts too closely to the peculiarities of an individual data set, rather than learning a target function that can be used for different data sets of the same category.

2.5 Neural Network

Neural networks are formally referred to as Artificial Neural Networks (ANN). They are a class of machine learning algorithm that has risen steadily in popularity over the previous decade. Training neural networks to solve problems is a process that is often referred to as “deep learning” colloquially. A neural network consists of connections of units or nodes called artificial neurons arranged in layers.

Neural networks can describe as computational graphs, which place mathematical operations into nodes that connect to each other. When the output of one node is the input of another, an arrow can be drawn from the first node to the second[8]. Every neural network diagram displays the computational graph for that network. Nodes in a neural network are referred to as neurons. There are many different variations of neural networks that currently used for various tasks.

2.5.1 Deep Feedforward Networks

The most basic version of a neural network is called a feedforward neural network, or a multilayer perceptron. A multilayer perceptron consists of artificial neurons arranged in sequential layers. The first layer of the network is comprised of the data, which is the input for the model. Each neuron typically corresponds to a dimension or variable in that dataset. The first layer takes the form of a matrix, which is transformed by matrix multiplication with a set of numbers referred to as weights that are often randomly initialized. A further level of

transformation can be provided to introduce non-linearity if an activation function is implemented. The neurons in the following layer of the neural network represent the transformed version of the first layer, following matrix multiplication with weights. Through this process, data is continually transformed in each consecutive layer, until it reaches the final layer or the output layer. This process collectively referred as a forward pass [8].

In supervised learning, the output of a neural network is checked for accuracy through a specified criterion. An algorithm is then implemented to adjust the weights of each layer by a small amount, with the goal of producing a more accurate output. Another forward pass is then conducted, and this process repeats in many iterations until a neural network has “learned” how to transform data to make consistently accurate predictions.

2.6 Tensor

A tensor is a mathematical object that can be used to represent any N-dimensional data structure. A tensor is analogous to a container for data that can apply mathematical operations. A1-dimensional tensor is a vector; a 2-dimensional tensor is a matrix, etc. Machine learning algorithms involve mathematical operations on data contained within tensors.

1. One-dimensional tensor = vector.

$$\begin{bmatrix} 2 \\ 5 \\ 1 \end{bmatrix}$$

2. Two-dimensional tensor = matrix.

$$\begin{bmatrix} 1 & 5 & 7 \\ 4 & 4 & 3 \\ 2 & 6 & 9 \end{bmatrix}$$

2.7 Matrix Multiplication

If matrix A is a matrix with dimensions of n x m and matrix B is a matrix of m x p dimensions, then the product of A X B is a matrix of n x p dimensions. Each entry in the new matrix is given by multiplying the entries of a row in A by a column in B and summing the results. Matrix multiplication is not a commutative operation: the product of A X B does not equal the product of B X A. Additionally, matrix multiplication can only work if the column number in the first matrix matches the row number in the second matrix [9].

$$\begin{bmatrix} 2 & 4 & 5 \\ 1 & 0 & 7 \end{bmatrix} \begin{bmatrix} x & a \\ y & b \\ z & c \end{bmatrix} = \begin{bmatrix} 2x + 4y + 5z & 2a + 4b + 5c \\ x + 7z & a + 7c \end{bmatrix}$$

2.8 Hadamard Product

The Hadamard Product is a mathematical operation that is conducted between two matrices. It can only be calculated for two matrices of the same

dimensions. The Hadamard Product of two matrices is a matrix in which each element is the product of corresponding elements in the first two matrices.

$$\begin{bmatrix} 2 & 7 \\ 3 & 5 \end{bmatrix} \odot \begin{bmatrix} 1 & 1 \\ 0 & 0 \end{bmatrix} = \begin{bmatrix} (2*1) & (7*1) \\ (3*0) & (5*0) \end{bmatrix} = \begin{bmatrix} 2 & 7 \\ 0 & 0 \end{bmatrix}$$

2.9 Activation Function

Activation functions are transformations that influence the output from a layer of neurons in a neural network. Activation functions can act as gates that block or allow neurons pass their values to the next layer based on a threshold, or they can transform the output of a neuron based on a continuous or discrete limit.

Activation functions are vital in neural networks because they introduce non-linearity into the network. Besides, without activation functions between layers, each neural network layer would be a linear transformation of the previous layer. If this is the case, the target function between input and output is limited in its complexity, and the network likely fails to converge when tasked with solving a difficult non-convex optimization problem. By introducing non-linearity into a neural network training process, activation functions allow neural networks to find significantly more complex methods of mapping an input to an output [10].

2.10 Loss Function

Loss functions are a crucial part of neural networks. Loss function can also be referred to as cost functions. A loss function is a mathematical representation of the gap between a network's predictions and the correct values. The value of a loss function will always be positive, as it represents the inconsistency between forecasts and right values. Many different loss functions can be used in different situations [11]. For example, standard loss functions for regression problems are mean squared error and L1 loss. There is no way to quickly know which loss function will provide the best results for a given neural network experiment. Experimenting with multiple viable loss functions is a good practice for smaller scale problems where training time is not too cumbersome.

If a neural network has at least one hidden layer, its loss function will almost certainly be non-convex. For clarity, a convex function has a single global minimum. Minimizing a convex loss function is relatively simple, as an algorithm needs merely to descend towards a single global minimum. Unfortunately, neural networks have non-convex loss functions that are marked by multiple local minima, rather than a single global minimum.

2.11 Optimizer

If a neural network minimizes a loss function to the best of its abilities, it must acquire a way to find the lowest point on a very complex non-convex loss

function. Finding a minimum point is a complicated task, and this is the purpose of optimization algorithms [12].

Optimization algorithms can be separated into first-order optimization algorithms and second-order optimization algorithms. First-order optimization algorithms minimize a loss function concerning its gradient. A gradient is merely a vector containing the partial derivatives of a function. In other words, the gradient is the multivariable equivalent of a derivative in single variable calculus, which is the slope or instantaneous rate of changing the output regarding its input. Second order methods use the Hessian, which is the multivariable equivalent of the second derivative. A Hessian can be as the gradient of a function's gradient. First-order optimization methods are significantly less computationally costly than second-order optimization methods, and the following explanations and algorithms covered are all first-order optimization methods [13].

2.11.1 Gradient Descent

All of the popular first-order optimization algorithms use an approach known as gradient descent. Gradient descent optimizers, following a forward pass, calculate the gradient of the loss function concerning the network's parameters, mainly the weights. This gradient is calculated with an algorithm called backpropagation, which is a computational implementation of reverse mode differentiation. After the slope calculated, the weights are then adjusted in small steps in the opposite direction of the loss function gradients [14]. Then

another forward pass is calculated, and the loss function's gradient is again calculated, and weights are then adjusted. The goal of gradient descent algorithms is to descend along the slope to find an optimal solution.

2.11.2 Learning Rate

The size of each adjustment, or step along the gradient, is called the learning rate of an optimizer. If the learning rate is too small, an optimizer might take too long to train, as its progress towards an optimal solution will take too long. If the learning rate is too large, the optimizer might "overshoot" the local region that leads to a minimum and skips over that area of the loss function entirely. Finding the best learning rate is often a matter of intuition and experimentation [13].

2.11.2 Batch Size

The batch size of a neural network in training refers to the number of data samples that are sent through the network in a single forward pass to calculate the gradient of the loss function. A forward pass of all data samples in a neural network referred to as an epoch [11].

2.11.3 Stochastic Gradient Descent

The equation for stochastic gradient descent is:

$$\theta = \theta - \alpha * \nabla J(\theta)$$

In this equation, θ refers to the parameters updated. α refers to the learning rate or the size of the adjustment. ∇J(θ) refers to the gradient of the loss

function concerning the gradient. Collectively, α·∇J(θ) refers to the update of the parameters by the optimizer. In other words, stochastic gradient descent updates the parameters opposite the gradient of the loss function scaled by a constant called the learning rate [14].

2.11.4 Momentum

If a gradient descends much more steeply in one dimension than in others, stochastic gradient descent tends to oscillate when updating, and often fails to drop in the correct amount towards a local minimum. Momentum is a technique that can be added to stochastic gradient descent to address this. Momentum mitigates oscillation and emphasizes the correct direction for the algorithm to descend in. It does this by incorporating information from the last update into the current update [15].

In mathematical terms, if the update of stochastic gradient descent is called v, then the new update can be formulated via the following equation:

$$v_t = \mu * v_{t-1} + \alpha * \nabla J(\theta)$$

In this equation, μ refers to a fraction of the previous update. μ is often a value near 1. Simply put, the last update, or a scaled version almost equal the previous update is added to the learning rate times the gradient to create the new update. The algorithm then updates the parameters with the equation [14]:

$$\theta = \theta - v_t$$

or

$$\theta = \theta - (\mu * v_{t-1} + \alpha * \nabla J(\theta))$$

In simpler terms, momentum works much as it does in its classical physics definition. As the algorithm descends the gradient, it theoretically descends faster and faster. Momentum increases for terms with gradients pointing in the same direction and reduces the rate of updates for terms with gradients leading in opposite directions, which effectively accelerates the algorithms descent along the gradient and minimizes the oscillation of the optimizer [15].

2.12 Backpropagation

Neural networks are made computationally tractable with the implementation of the back-propagation algorithm. Backpropagation is a neural network specific implementation of a technique called reverse mode differentiation, which allows for the rapid calculation of derivatives [16].

A partial derivative shows how altering one value affects a-partially dependent value. Within the context of a computational graph, it shows the expansive effects of altering different node. To compute partial derivatives between nodes that are not directly connected, one must sum over all possible paths from one node to another while multiplying the partial derivatives of each edge of a path together [17]. This is one way to think about how the chain rule in multivariable calculus works.

This problem here is that the number of paths between different nodes explodes as a neural network gets larger, which quickly makes a typical application of the multivariate chain rule computationally intractable. Forward mode differentiation and reverse mode differentiation are two techniques that help address this. Both techniques merge paths together at each node, rather than summing over all possible paths individually. Forward mode differentiation starts at input to the graph, and tracks how it affects every node forward. The derivative of every node with respect to the input is calculated. Once this is done, the derivative of the output with respect to every input has been calculated. Reverse mode differentiation starts at the graphs output, and then moves backwards, giving the derivative of the output with respect to every node in one calculation [16].

If a graph has 100 inputs and one output, forward mode differentiation would have to move through the graph 100 times to get the derivative of the output with respect to all outputs. Reverse mode differentiation is able to get this same derivative while moving through the graph only once. For most neural networks, reverse mode differentiation is exponentially faster. The backpropagation algorithm, which applies reverse mode differentiation to neural networks, makes most neural networks computationally tractable.

CHAPTER THREE

AUTISM DIAGNOSTIC OBSERVATION SCHEDULE

3.1 Introduction

This section describes each module of the Autism Diagnostic Observation Schedule (ADOS) in detail. The section communicates the origin and parameters of the data used in this thesis. It includes the purpose of each module and the concepts that it covers. Each variable gets explained thoroughly. The section contains the significance of different scores for each variable, and lists the shortened encodings used in the data.

3.2 Autism Diagnostic Observation Schedule (ADOS)

ADOS is a tool for diagnosing and assessing autism. The procedure consists of a sequence of structured and semi-structured tasks that involve social interaction between the inspector and the participant. It is uesed to evaluate the potential for autism spectrum disorders within an individual [18].

3.3 ADOS Modules

ADOS modules are activities of social communicative sequences, structured situation, and unstructured situations that allow the examiner to

observe whether any behaviors occur that determine the presence of autism and other pervasive developmental disorders. The activities are tasks runs by the examiner to allow for a consistent observation of the participant. These activities contain several observationa items. The items are features of behavior that the inspector focuses on detecting throughout the task. The examiners rate each observation according to the coding rules and specific coding standards [19].

The ADOS has four modules which are Module 1, Module 2, Module 3 , and Module 4. The examiners select it based on the individual's expressive language level or chronological age level. Each module can be administered in the range of 45 minutes to 100 minutes. It is suitable for children and adults of different ages and language levels reaching non-speaking to fluently [19].

In general Module 1 and Module 2 are designed for children who are not verbally fluent. Module 3 and Module 4 developed for participants who are verbally fluent. However, the difference between Module 3 and Module 4 is that Module 3 observes through play along with interview questions to collect information about social communication, while Module 4 entirely depends on interview questions and conversation [19].

The table below shows the different ages and language levels between the modules [19].

Table 1. ADOS Modules Ages and Language Levels

Language level	Chronological age range	ADOS Module
No speech/ simple phrase	31 months and older	Module 1
Phrase speech not verbally fluent	Any age	Module 2
Fluent speech	Children/ Adolescent Usually under 16	Module 3
Fluent speech	Adolescent / Adult	Module 4

As mentioned earlier, the examiner runs different tasks on the participant for observation which are call activities. The table below shows a list of the activities between modules [19].

Table 2. Modules Activities

***** optional

3.3.1 Module 1

Module 1 is dedicated to children ages 31 months and older who have language levels of no speech to a simple phrase or single words. This module also can be used for adolescent and adult who have the same language level.

Module 1 of the ADOS consists of 10 activities with 29 observation items. Each item is rated by the examiner according to 5 main categories, "Language and Communication," "Reciprocal Social Interaction," "Play," "Stereotyped Behaviors and Restricted Interests," and "Other Abnormal Behaviors." [18]

The table below shows Observation Items for Language and Communication section. In this section, there are 8 observation items for the examiner to rate according specific coding standards [19].

Table 3. Module 1 Section 1 Observation Items

Section A: Language and Communication	
Observation Items	**Abbreviation**
A1. Overall level of non-echoed spoken language	(OLANG)
A2. Frequency of Spontaneous Vocalization Directed to Others	(FVOC)

A3. Intonation of Vocalizations or Verbalizations	(INTON)
A4. Immediate Echolalia	(IECHO)
A5. Stereotyped/Idiosyncratic Use of Words or Phrases	(STEREO)
A6. Use of Another's Body	(UOTHER)
A7. Pointing	(POINT)
A8. Gestures	(GEST)

The table below shows Observation Items for Reciprocal Social Interaction section. In this section, there are 12 observation items for the examiner to rate according specific coding standards [19].

3.3.2 Module 2

Module 2 is dedicated to children of any age who have language level of some phrase speech but not verbally fluent. This module also can be used for adolescent and adult who have the same language level. Children under age of 3 who are verbally fluent are examined with this module even if they meet Module 3 standards.

Module 2 of the ADOS consists of 14 activities with 28 observation items. Each item is rated by the examiner according to 5 main categories, “Language and Communication,” ” Reciprocal Social Interaction,” ” Play,” ” Stereotyped Behaviors and Restricted Interests,” and ” Other Abnormal Behaviors.”[19]

The table below shows Observation Items for Language and Communication section. In this section, there are 7 observation items for the examiner to rate according specific coding standards [19].

3.3.3 Module 3

Module 3 is dedicated to children and adolescent between 4 to 15 years of age who have verbally fluent language levels. As mentioned previously, children

under age of 2 who are verbally fluent will be examined by Module 2 even if they meet Module 3 standards.

Module 3 of the ADOS consists of 14 activities with 28 observation items. Each item is rated by the examiner according to 5 main categories, “Language and Communication,” ” Reciprocal Social Interaction,” ” Imagination,” ” Stereotyped Behaviors and Restricted Interests,” and ” Other Abnormal Behaviors.” [19]

The table below shows Observation Items for Language and Communication section. In this section, there are 9 observation items for the examiner to rate according specific coding standards [19].

Table 13. Module 3 Section 1 Observation Items

Section A: Language and Communication	
Observation Items	**Abbreviation**
A1. Overall level of non-echoed spoken language	(OLANG)
A2. Speech Abnormalities Associated With Autism	(SPABN)
A3. Immediate Echolalia	(IECHO)
A4. Stereotyped/Idiosyncratic Use of Words or Phrases	(STEREO)
A5. Offers Information	(OINFO)
A6. Asks for Information	(AINFO)
A7. Reporting of Events	(REPRT)
A8. Conversation	(CONVS)
A9. Descriptive, Conventional, Instrumental or informational Gestures	(DGEST)

The table below shows Observation Items for Reciprocal Social Interaction section. In this section, there are 10 observation items for the examiner to rate according specific coding standards [19].

Table 14. Module 3 Section 2 Observation Items

Section B: Reciprocal Social Interaction	
Observation Items	**Abbreviation**
B1. Unusual Eye Contact	(UEYE)
B2. Facial Expressions Directed to Others	(FACEO)
B3.Language Production and Linked Nonverbal Communication	(LLNVC)
B4. Shared Enjoyment in Interaction	(SHIRJ)
B5. Comment on Others' Emotions/Empathy	(EMPTH)
B6. Insight Into Typical Social Situations and Relationships	(INSIG)
B7. Quality of Social Overtures	(QSOV)
B8. Quality of Social Response	(QSRES)
B9. Amount of Reciprocal Social Communication	(ARSOC)
B10. Overall Quality of Rapport	(OQRAP)

The table below shows Observation Items for Imagination section. In this section, there is 1 observation item for the examiner to rate according specific coding standards [19].

Table 15. Module 3 Section 3 Observation Items

Section C: Imagination	
Observation Items	**Abbreviation**
C2. Imagination/Creativity	(IMGCR)

The table below shows Observation Items for Stereotyped Behaviors and Restricted Interests section. In this section, there are 5 observation items for the examiner to rate according specific coding standards [19].

Table 16. Module 3 Section 4 Observation Items

Section D: Stereotyped Behaviors and Restricted Interests	
Observation Items	**Abbreviation**
D1. Unusual Sensory Interest in Play Material/Person	(USENS)
D2. Hand and Finger and Other Complex Mannerisms	(OMAN)
D3. Self-Injurious Behavior	(SELFINJ)
D4. Excessive Interest in or References to Unusual or Highly Specific Topics or Objects or Repetitive Behaviors	(TOPIC)
D5. Compulsions or Rituals	(RITL)

The table below shows Observation Items for Other Abnormal Behaviors section. In this section, there are 3 observation items for the examiner to rate according specific coding standards [19].

Section E: Other Abnormal Behaviors	
Observation Items	**Abbreviation**
E1.Overactivity/Agitation	(ACTIVE)
E2. Tantrums, Aggression, Negative or Disruptive Behavior	(AGG)
E3. Anxiety	(ANXTY)

3.3.4 Module 4

Module 4 is dedicated to older adolescent and adult of age16 years and older who have verbally fluent language level. As mentioned previously there are slight differences between Module 4 and 3. Module 4 depends on interview questions and conversation while Module 3 depends on the play along with interview questions.

Module 4 of the ADOS consists of 15 activities with 31 observation items. Each item is rated by the examiner according to 5 main categories, “Language and Communication,” ” Reciprocal Social Interaction,” ” Imagination,” "Stereotyped Behaviors and Restricted Interests,” and ” Other Abnormal Behaviors.”[19]

The table below shows Observation Items for Language and Communication section. In this section, there are 10 observation items for the examiner to rate according specific coding standards [19].

Table 18. Module 4 Section 1 Observation Items

3.4 ADOS Coding Conventions

The table below shows coding conventions applied to ADOS modules coding sections [19].

Table 23. ADOS Coding Convention Modules

Coding Rate	Convention
0	No evidence of abnormality in the behavior according to the specifications. The absence of defect as specified does not imply the expression is normal.
1	The behavior is slightly or mildly unusual yet not an exact match to the type specified but not grossly abnormal.
2	The behavior is an exact match to the defined abnormality. At this level, the severity of coding defect will vary according to the item.
3	The behavior is blatantly abnormal and interferes with the assessment, or the behavior is limited therefore making it impossible to make a qualitative evaluation.
4	It shows that test subject displayed no instinctive use of words or anything close to a word during the entire ADOS administration
7	an abnormal behavior yet, it not covered by the other ratings.
8	The behavior in question did not occur and/or the rating is not applicable

9	The item cannot rate due to some reason other than that listed for a code 8, such as if examiner commits an error and does not administer a particular ADOS activity. This code provides examiners with a consistent way to rate items that cannot measure and allowing it to use for any item.

The coding ratings range from 0 (abnormality specified is absent) through 2 or 3 (defect determined is present). Optimal or expected performance detailed in the code for a rating of 0, and partial, minimal, and/or wavering production described in the rest of the codes. In clinical practice, codes of 0, 1, 2, and 3 are the ones often considered most. Ratings of 8 or 9 can use for anything that is not applicable or that otherwise cannot be coded, as such it should be used sparingly because of all the missing data, including 8s or 9s, must change to scores of 0 on the algorithm [19].

3.5 ADOS DATA

The ADOS records of the participants can found in the Autism Genetic Resource Exchange (AGRE).

3.5.1 AGRE

AGRE is a non-profit DNA repository and family registry. It has a database of biomaterials, genotypic and phenotypic data that is made available to researchers. It is a central shared resource for studies on autism and related

disorders. It has data from 1700+ families with 3300+ affected individuals with an Autism Spectrum Disorder. It contains Clinical and biomaterial data for over 500 twin families [20]. However, accessing the data requires approval. Approval information can be found in Appendix A.

3.5.2 Data information

The AGRE provided all records following the approvel prosses. Patient evaluation results for each module were included.

Module 1 data contains1055 individuals, Module 2 contains 602 individuals, Module 3 contains 1158 individuals, and Module 4 contains 264 individuals. The data was collected between the years 2002 and 2015.

CHAPTER FOUR

MODEL DESIGN

4.1 Introduction

This section covers all details relevant to the design of the model used in this thesis. The information includes details about the Python machine learning ecosystem, the type of model used, the unique architectural aspects of the model used, the reasoning behind these aspects, and their implementation in math and code.

4.2 Python Machine Learning Tools Used

4.2.1 Numpy

Numpy is a Python package used for scientific computing. It contains functions that allow for robust array computations, advanced math such as linear algebra and Fourier transformations, and can act as an efficient container of different types of data. Numpy can very easily integrate with other Python libraries and frameworks for specific purposes, such as neural networks and machine learning [21].

4.2.1 Pandas

Pandas is a Python library that provides useful data structures and tools for data analysis. In some ways, pandas is analogous to Excel for Python [22].

4.2.2 Scikit-Learn

Scikit-learn is a Python library for machine learning tasks. It provides many functions for regression, classification, dimensionality reduction, clustering, model selection, and preprocessing [23].

4.2.3 Matplotlib

Matplotlib is a Python library that is used for convenient graphing and data visualizations [24].

4.2.4 Jupyter Notebook

A Jupyter Notebook is a document, which can contain both computer code in specific languages (Python included) and rich text elements (charts, graphs, and so forth). In the Jupyter Notebook, code is can be written and executed in the same document. Lines of code can divide into modular cells that can be executed individually. Jupyter notebooks run in a server-client application that operated through a web browser online or offline. When a notebook document is opened, a kernel corresponding to the language of choice (in this case, the iPython kernel) gets launched. When a cell of code is executed, the kernel runs the computations and produces the output underneath the block [25].

4.3 PyTorch

PyTorch is a Python constructed deep learning research framework, which offers flexibility and high speed. It consists of several libraries such as tensor computation that uses strong GPU integration, which is the key of PyTorch components. Also, it contains tape-based autograd that supports all differentiable tensor operations. Moreover, it contains a neural networks library that is tightly integrated with automatic differentiation and optimization, which features famous optimizers such as Stochastic Gradient Descent, RMSprop, and Adam [26].

4.3.1 Pytorch Components

4.3.1.1 Tensor Computations

Tensors are the core of PyTorch. They are n-dimensional arrays and form the fundamental building blocks for many algorithms including neural networks. PyTorch tensors are functionally equivalent to numpy arrays , but can be operated upon by GPU's provide significantly faster calculations for many machine-learning tasks, including neural networks. A PyTorch tensor can cast into a GPU-specific data type, and a model comprised of these tensors can be trained on a GPU significantly faster than on a CPU [27].

4.3.1.2 Autograd Mechanics

The autograd package in PyTorch provides the functionality of automatic differentiation. Automatic differentiation is used to quickly evaluate the derivative

of a function specified by a computer program by repeatedly applying the chain rule to elementary operations [27].

Neural networks are typically trained with back-propagation using a unique form of automatic differentiation called reverse mode automatic differentiation. When using the autograd package, each forward pass of a neural network defines a computational graph with tensors as nodes. Each tensor is wrapped in a Variable object that represents a node in the computational graph [27]. Back-propagation through this graph allows for the quick computation of gradients. PyTorch autograd implementation is not unique; however, it is swift compared to what is offered by many competing frameworks.

4.3.1.3 Torch.nn

Torch.nn is a library in PyTorch, which allows the user to build neural networks conveniently. It provides a high degree of abstraction over raw computational graphs, which makes it simpler to develop and organize neural networks of all sizes based on layer types, dimensions, and activation functions [26]. Torch.nn is similar to Keras, which providesthe same functionality to users of other frameworks like TensorFlow and Theano.

The nn package contains Modules, which are similar to neural network layers. The modules take input and compute an output, and it can hold an internal state if needed. Also, nn contains a multitude of loss functions and activations for timely implementation. All commonly implemented loss and

activation functions are present in PyTorch, allowing for easy experimentation with different combinations [27].

It is possible to build custom nn modules that are more complex than existing modules, and this can be done by creating a subclass and defining a specific forward operation that receives inputs and computes outputs.

4.3.1.4 Torch.optim

The optim package provides an abstraction for optimization algorithms rather than manually writing code to update weights for Variables in a model. Powerful and popular optimization algorithms such as AdaGrad and Adam can conveniently implement in a model [27].

4.3.2 PyTorch Unique Features and Advantages

4.3.2.1 Tight Integration with Python Language

PyTorch has multiple of advantages over other deep learning frameworks. It is more tightly integrated with the Python language than competitors such as TensorFlow. PyTorch is underlying C/C++ code is tailored explicitly for conveniently working with Python. By comparison, TensorFlow was first built entirely in C/C++ and then bound to Python. Using PyTorch is like using other Python libraries, such as numpy or scipy. Layers can be written from scratch in Python and incorporated into PyTorch models. The code can execute on a line-by-line basis, which allows for easier debugging. PyTorch also displays the

dimensionality of all tensors within a model, which also assists with debugging [27].

PyTorch can easily be extended with custom Python code. This allows users to build models of any level of uniqueness and complexity while still enjoying PyTorch's lightning fast computational speed. The tighter integration of PyTorch with the Python language makes innovation within PyTorch significantly more comfortable than in other frameworks, like TensorFlow.

4.3.2.2 Dynamic Computational Graphs

PyTorch defines its computational graphs dynamically, which contrasts from the static graph methods used by other Python deep learning frameworks. All deep learning frameworks define neural networks as directed acyclic graphs. Most structures generate a graph once, and then continually re-use it when training the model. PyTorch, on the other hand, creates a graph with each forward pass. This dynamic computational graph generation enables a higher degree of flexibility in training in many ways, such as allowing inputs of different sizes dynamically within the same data set. Any aspect of the computational graph can be adjusted on the fly with control flow, from the dimensions of hidden layers to the number of hidden layers, to the activation function used between layers [27].

4.3.2.3 Exceptional Speed and Flexibility

PyTorch also has a low framework overhead and support for acceleration libraries featured by hardware manufacturers. Integration with Nvidia's acceleration libraries CUDA and CuDNN is a notable perk of PyTorch.

PyTorch is also exceptionally fast for training small and large neural networks. Memory allocation is also hyper-efficient, as PyTorch contains custom memory allocators for GPU's [27]. PyTorch tensors use the same memory allocation as numpy arrays, which allows for data to be converted between PyTorch and numpy structures significantly faster than it can in TensorFlow. Within the subjective experience of this experiment, PyTorch trained small neural networks markedly quicker than TensorFlow did.

4.3.3 CUDA

CUDA is a parallel computing platform developed by NVIDIA for use on GPU's. CUDA allows for significantly faster computing with GPU's and is tightly integrated with several popular machine learning frameworks, including PyTorch [28].

4.4 Autoencoder

Autoencoders are a particular type of feedforward neural network. They recreate the model's input as their target. Naturally, the output layer of an autoencoder has the same dimensions as the input layer. Autoencoders have

hidden layers smaller than either the input or output layer. An autoencoder compresses its inputs in the hidden layers and then attempts to reconstruct the input as its output [29].

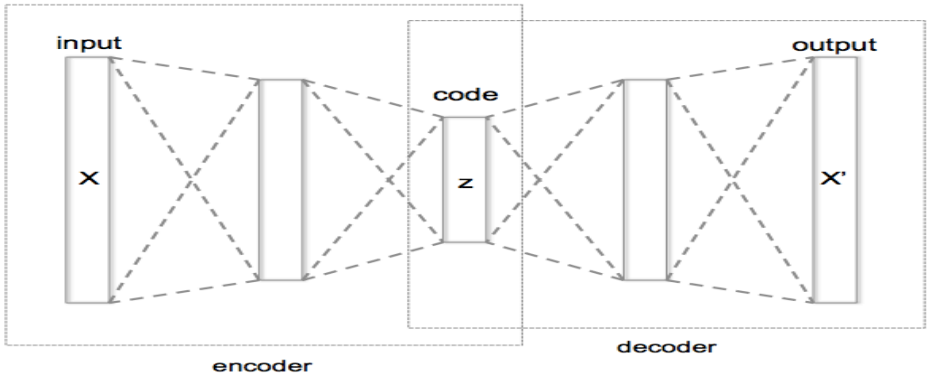

Figure 1. Autoencoder [30]

The first half of an autoencoder is called the encoder. The encoder includes the input layer and any hidden layers up to the smallest hidden layer. The most smallest hidden layer in an autoencoder represents the most compressed representation of the input. The first half of an autoencoder is called the encoder because by compressing the input, it is effectively creating a concise, encoded representation of the input [31].

The second half of an autoencoder is called the decoder. The decoder includes progressively wider hidden layers following the encoded layer, all the way until the output layer while attempting to reconstruct the input. This section of an autoencoder is called a decoder because it tries to recreate the original

input from its encoded representation, without “knowing” what the original input looked like, therefore acting as a “decoder” of sorts [31].

Autoencoders have very few practical applications currently. These neural networks mostly used for experimental causes. They are attractive to researchers because of their potential for large-scale, intelligent dimensionality reduction. If neural networks are used for large-scale unsupervised learning, autoencoders might be able to function as a memory of sorts by compressing the massive amounts of data an algorithm might parse through into a condensed representation, and then deconstructing that representation to restore the full dimensionality of the original data.

4.4.1 Reasons for Using Autoencoder

Applying autoencoders to the Autism Diagnostic Observation Schedule is a novel application of autoencoders. Since autoencoders are a type of neural network, their effectiveness scales very well with the amount of data available. Neural networks also scale in effectiveness with more significant computational resources. Since computing power is increasing, and the amount of available ADOS data is increasing as well, autoencoders have the potential to be an algorithm of considerable interest in the future. Other dimensionality reduction methods such as principal components analysis (PCA) have been applied to the ADOS by other researchers in recent years [32]. These algorithms, as well as all different “shallow” machine learning algorithms, are increasingly less relevant

with every year, whereas neural networks are frequently interesting, relevant, and efficient. For this reason, autoencoders chosen for this thesis.

4.5 Autoencoder with Special Connection

4.5.1 Special Connections with Binary Mask Matrix

Typically, the computational graph of a neural network features fully connected layers. That is, each node in a layer connects to each node in the following layer. In effect, that means that each neuron in one layer has an impact on every neuron in the next layer. In this experiment, each neuron in the input layer corresponds to a variable within ADOS. Similarly, each neuron in the hidden layer of the autoencoder corresponds to a new variable in the reduced length diagnostic. Every neuron in the input layer that connects with a neuron in the hidden layer represents the content of an ADOS items impacting the content of reduced diagnostic items.

The ADOS features different sections with significantly different subject material. If an autoencoder with fully connected layers were to be used, that would indicate that questions from all sections should be indiscriminately combined in a reduced diagnostic. Given the conceptual differences between sections, this does not seem like a logical approach. Therefore, it is necessary to enforce specific connections between layers in the autoencoder.

In the experiment's design, the reduced length diagnostic has the same sectional structure as the original diagnostic. The only difference is that each section has fewer variables. Each variable in the original diagnostic influences every variable in the corresponding section of the reduced diagnostic, and no other variables in the reduced diagnostic whatsoever.

In other words, connections between neurons in each layer occur in discrete groups, rather than ubiquitously. This is achieved through the use of a binary adjacency matrix called a mask. The mask matrix exclusively consists of 0's and 1's. The 0's and 1's correspond with connections that are to be removed and enforced respectively.

During each forward pass for the network, the binary mask matrix is applied to the weight matrix before the weights and the inputs are multiplied together. The mask matrix and the weight matrix have the same dimensions, and they are combined with an element wise multiplication operation known as the Hadamard product. In this operation, corresponding values in each matrix are multiplied together. The result of this operation is the preservation of certain weights, and the removal of others by setting them to a value of 0. Once the weight matrix is combined with the inputs through matrix multiplication, every weight corresponding to desired connections is preserved and every weight corresponding to undesired connections is set to 0. The diagrams below are Hadamard Product of Weight Matrix and Binary Mask Matrix for Module 1, 2, 3 and 4. Find the other Hadamard Product Diagrams in Appendix B.

Module1 Hadamard Product for 2920 Dimension

$$\begin{bmatrix} w_{1,1} & \cdots & w_{1,5} & w_{1,6} & \cdots & w_{1,14} & w_{1,15} & \cdots & w_{1,20} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ w_{8,1} & \cdots & w_{8,5} & w_{8,6} & \cdots & w_{8,14} & w_{8,15} & \cdots & w_{8,20} \\ w_{9,1} & \cdots & w_{9,5} & w_{9,6} & \cdots & w_{9,14} & w_{9,15} & \cdots & w_{9,20} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ w_{20,1} & \cdots & w_{20,5} & w_{20,6} & \cdots & w_{20,14} & w_{20,15} & \cdots & w_{20,20} \\ w_{21,1} & \cdots & w_{21,5} & w_{21,6} & \cdots & w_{21,14} & w_{21,15} & \cdots & w_{21,20} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ w_{29,1} & \cdots & w_{29,5} & w_{29,6} & \cdots & w_{29,14} & w_{29,15} & \cdots & w_{29,20} \end{bmatrix} \odot \begin{bmatrix} 1_{1,1} & \cdots & 1_{1,5} & 0_{1,6} & \cdots & 0_{1,14} & 0_{1,15} & \cdots & 0_{1,20} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 1_{8,1} & \cdots & 1_{8,5} & 0_{8,6} & \cdots & 0_{8,14} & 0_{8,15} & \cdots & 0_{8,20} \\ 0_{9,1} & \cdots & 0_{9,5} & 1_{9,6} & \cdots & 1_{9,14} & 0_{9,15} & \cdots & 0_{9,20} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0_{20,1} & \cdots & 0_{20,5} & 1_{20,6} & \cdots & 1_{20,14} & 0_{20,15} & \cdots & 0_{20,20} \\ 0_{21,1} & \cdots & 0_{21,5} & 0_{21,6} & \cdots & 0_{21,14} & 1_{21,15} & \cdots & 1_{21,20} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0_{29,1} & \cdots & 0_{29,5} & 0_{29,6} & \cdots & 0_{29,14} & 1_{29,15} & \cdots & 1_{29,20} \end{bmatrix}$$

$$= \begin{bmatrix} w_{1,1} & \cdots & w_{1,5} & 0_{1,6} & \cdots & 0_{1,14} & 0_{1,15} & \cdots & 0_{1,20} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ w_{8,1} & \cdots & w_{8,5} & 0_{8,6} & \cdots & 0_{8,14} & 0_{8,15} & \cdots & 0_{8,20} \\ 0_{9,1} & \cdots & 0_{9,5} & w_{9,6} & \cdots & w_{9,14} & 0_{9,15} & \cdots & 0_{9,20} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0_{20,1} & \cdots & 0_{20,5} & w_{20,6} & \cdots & w_{20,14} & 0_{20,15} & \cdots & 0_{20,20} \\ 0_{21,1} & \cdots & 0_{21,5} & 0_{21,6} & \cdots & 0_{21,14} & w_{21,15} & \cdots & w_{21,20} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0_{29,1} & \cdots & 0_{29,5} & 0_{29,6} & \cdots & 0_{29,14} & w_{29,15} & \cdots & w_{29,20} \end{bmatrix}$$

$$= \begin{bmatrix} w_{1,1} & \cdots & w_{1,6} & 0_{1,7} & \cdots & 0_{1,13} & 0_{1,14} & \cdots & 0_{1,19} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ w_{10,1} & \cdots & w_{10,6} & 0_{10,7} & \cdots & 0_{10,13} & 0_{10,14} & \cdots & 0_{10,19} \\ 0_{11,1} & \cdots & 0_{11,6} & w_{11,7} & \cdots & w_{11,13} & 0_{11,14} & \cdots & 0_{11,19} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0_{22,1} & \cdots & 0_{22,6} & w_{22,7} & \cdots & w_{22,13} & 0_{22,14} & \cdots & 0_{22,19} \\ 0_{23,1} & \cdots & 0_{23,6} & 0_{23,7} & \cdots & 0_{23,13} & w_{23,14} & \cdots & w_{23,19} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0_{31,1} & \cdots & 0_{31,6} & 0_{31,7} & \cdots & 0_{31,13} & w_{31,14} & \cdots & w_{31,19} \end{bmatrix}$$

Figure 5. Module 4 Hadamard Product for 3119 Dimensions

The first matrix, is the weight matrix. This second matrix, the binary mask matrix, is comprised of ones and zeros corresponding to the desired and undesired connections. Before the weights are applied to the inputs, the network will constrain the weights through element-wise multiplication between the mask and the weight matrices. The new weight matrix is the Hadamard product of the mask and weight matrices.

As can be seen in the diagram below, implementing the mask matrix in a forward pass erases all undesired connections. The only connections between nodes in layers are connections that correspond to specific sections of the ADOS. Find The diagrams in Appendix C.

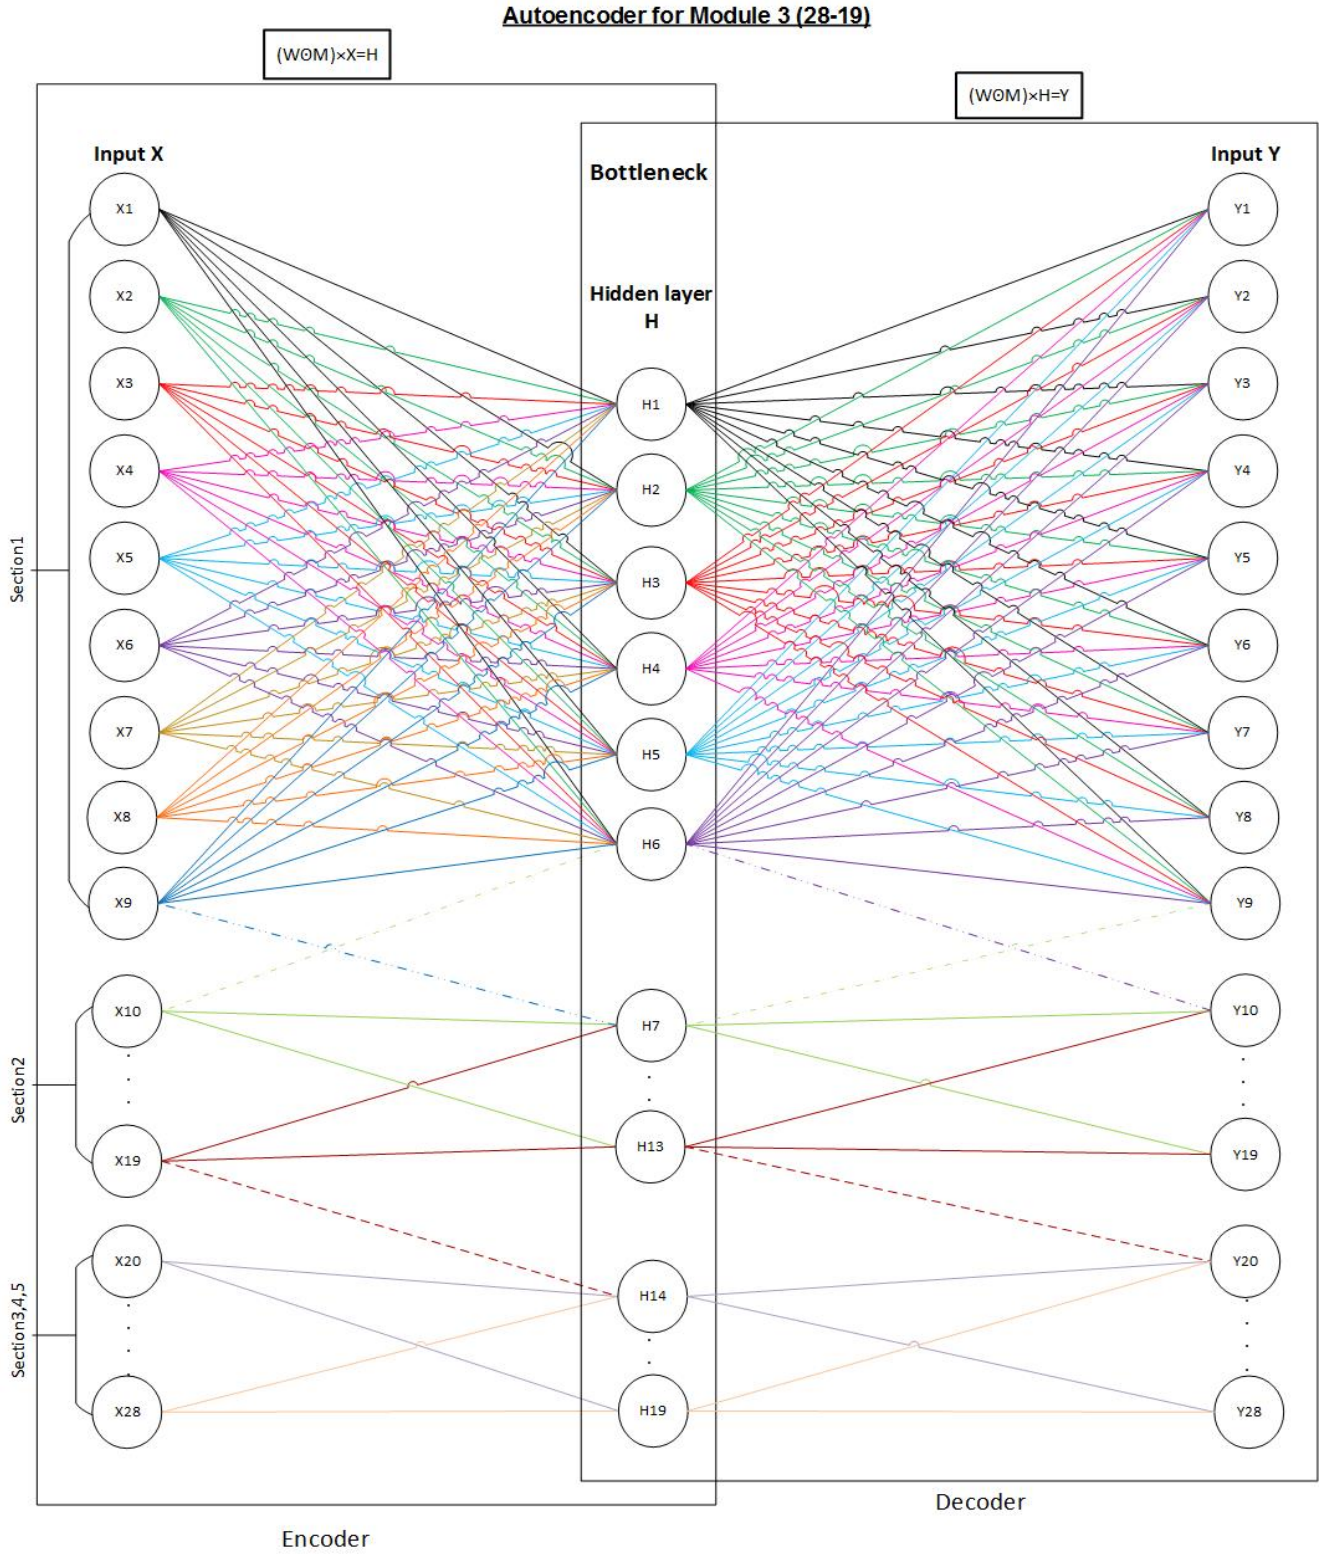

Figure 8. Module 3 Autoencoder with Hidden Layer of Size 19

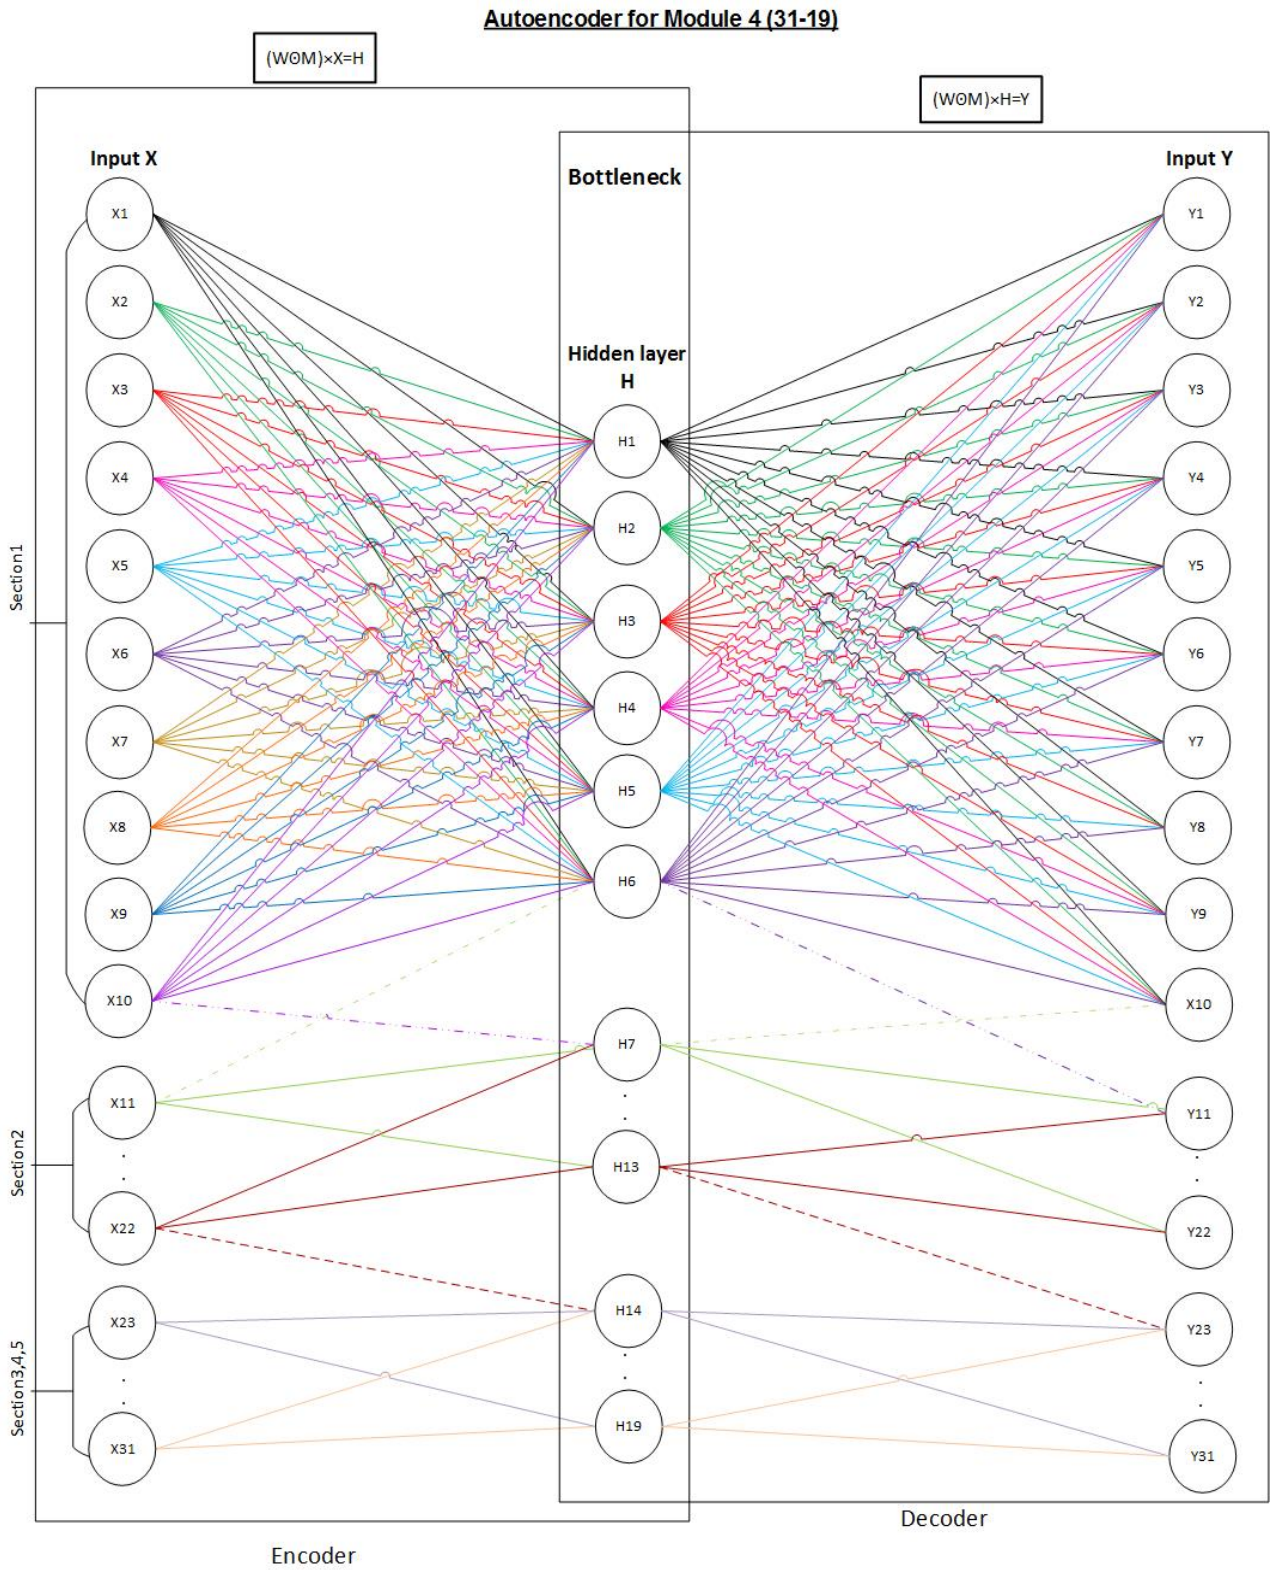

Figure 9. Module 4 Autoencoder with Hidden Layer of Size 19

4.5.2 Creating Mask in PyTorch

The binary mask used for the special connections between layers was originally created as a *numpy* array prior to its importation into PyTorch. PyTorch tensors are generally created from *numpy* arrays, so this intermediate step was required. The mask tensor was created as a PyTorch “FloatTensor” in order to match with the tensor type of the model’s weights. The tensor was then converted into a CUDA-specified tensor type stored on the GPU.

The mask for each autoencoder decoder layer is simply a transposition of the mask for each autoencoder encoder layer. For example, the mask that works for a reduction from 29 to 23 dimensions is simply a transposition of the mask that expands 23 dimensions for 29 dimensions. Therefore, for the sake of convenience mask, each decoder mask was simply created by transposing the corresponding encoder mask.

4.5.3 Incorporating Mask into Model

PyTorch allows a user to build custom modules for its nn package. Modules in nn function as neural network layers. Building a new module requires creating a custom subclass with a unique forward pass that receives Variables as inputs and computes Variables as outputs.

This experiment features custom layers that feature the aforementioned binary mask to selectively enforce and eliminate connections in a manner consistent with the sectional structure of the Autism Diagnostic Observation

Schedule. The forward pass of each layer is altered to update the weights by taking the Hadamard Product, or element-wise multiplication product, of the weight matrix and the binary mask matrix before applying the weights to the input Variable via matrix multiplication.

Otherwise, the custom module functions exactly like a standard feedforward neural network layer. The layer takes an array as an input and multiplies it through a weight matrix. The output of this operation becomes the input of the next layer in the neural network. In the case of PyTorch, the input array is a Torch tensor for GPU computation wrapped as a differentiable object called a Variable. The tensor inside this variable represent the data, which is multiplied by a weight matrix in which the undesired connections have already been eliminated through element-wise multiplication with the mask matrix or in other words the Hadamard Product.

The custom module for the masked layers created by altering the source code for PyTorch regular linear layers used in a standard feedforward neural network. These layers involve matrix multiplication between weights and inputs. Before this step, the code was added to modify the weight matrix through element-wise multiplication with the corresponding mask matrix.

4.6 Autoencoder Architecture

The input layer of each module's architecture corresponds to the number of variables in that module. Since autoencoders attempt the reconstruct their input as their output, the output layer for each autoencoder has to have the same number of neurons as the input layer. The only things to determine, in terms of autoencoder architecture, were the number of hidden layers, and the size of each hidden layer, with the smallest hidden layer being the most important, since it represents the encoded representation of the diagnostic.

When evaluating the architecture of the autoencoder, it is critical to keep the project's larger purpose in mind. The purpose of this thesis is to use an autoencoder to develop a viable reduced length diagnostic, rather than find the smallest possible encoded representation that an autoencoder can encode and then accurately decode. Likewise, the goal is to subjectively comprehend the variables that go into the encoded representation, and enforce specialized connections between layers to stay true to the sectional structure of the diagnostic.

In light of the goal of making sense of the variables that go into the reduced diagnostic, it made sense to have as few hidden layers as possible. First, autoencoders with three hidden layers were tested for Module 1. An intermediate encoding layer and an intermediate decoding layer helped bridge the gaps between the input, encoding, and reconstructed output. While this approach yielded a very accurate reconstruction, it was difficult to keep track of

the underlying concepts behind variables, or neurons, in the reduced diagnostic within the context of the original variables of the diagnostic. For that reason, autoencoders with a single hidden layer were chosen, since it is easier to keep track of the presence of input variables within the reduced diagnostic.

4.6.1 Autoencoder Pipeline

4.6.1.1 Building Autoencoders in PyTorch

The *nn* abstraction method was used to build the autoencoders. *NN* allows for a model to built as a combination of layers and activation functions. Since the masked layers had built as custom *nn* modules, these layers could simply be stacked to form the autoencoder in Pytorch.

Over the course of this thesis, multiple autoencoders were trained for different reduced length diagnostics for each module. The dimensions of every autoencoder are listed below.

4.6.2 List of Autoencoder Architectures Tested

4.6.2.1 Module 1

Module 1 contains 29 variables that are measured. The input layer of each autoencoder for Module 1 therefore contains 29 neurons to represent these original 29 variables. The dimensions of the output layer of each autoencoder match the dimensions of the input layer. Over the course of this thesis, four separate autoencoder structures for this module were tested, each with a single

hidden layer representing the reduced diagnostic. The only differences between these four autoencoders were the connections and the hidden layer size. Hidden layer sizes of 20 neurons, 21 neurons, 22 neurons, and 23 neurons were tested. During an earlier phase of experimentation, hidden layer sizes slightly smaller than 20 neurons were tested. During these trials, the accuracy of the reconstruction was significantly worse. Therefore, nothing below 20 neurons was used in the final phase of the experiment for Module 1.

4.6.2.1 Modules 2, 3 and 4

Modules 2, 3, and 4 each had four autoencoders trained for them. All autoencoders consisted of a single hidden layer. Each module's experimentation involved training autoencoders with hidden layer dimensions of 19, 20, 21, and 22 neurons. The only difference between the autoencoders for the different modules involved the dimensions of the input and output layers. Module 2 contains 28 variables. Module 3 also contains 28 variables. Module 4 contains 31 variables. The input and output dimensions of their respective autoencoders contain numbers of neurons that match the number of variables.

4.6.3 Reasons for the Lower Limit in Dimensionality Reduction

The purpose of this experiment was to test the possibility of a coherent reduced version of the Autism Diagnostic Observation Schedule. Therefore, it did not make sense to decrease the dimensionality of the data as much as algorithmically possible, since a reduction of too large a magnitude would be

inconsistent with the project's goal. The smallest hidden layer sizes of the autoencoders tested in this experiment represent multiple variables eliminated from each section of the corresponding module. Reducing dimensionality further seemed excessive from a subjective standpoint within the context of finding a viable reduced diagnostic size. The lowest dimensionality reductions involved removing multiple variables per section. Removing even more variables would not have left enough variables to cover the diversity of different concepts on the ADOS.

4.6.4 Selecting Regression Over Classification

This experiment was treated as a regression problem rather than a classification problem. Regression problems involve making predictions about a continuous variable, whereas classification problems involve making predictions about categorical variables. In regression problems, loss functions involve errors between predictions and targets. In classification, loss functions attempt to optimize classification accuracy as a binary procedure.

The scores of different variables on the ADOS all take the form of ordinal variables. Only integer values exist, but the hierarchy of the integers has a meaning, unlike in a strict classification problem. Because of the ordinal nature of ADOS scores, reconstructing the input was treated as a high dimensional regression problem, with appropriate loss functions. To make sure that the

reconstructions were comparable to the input, values were rounded to the nearest integer.

4.7 Hyperparameter Tuning

The most important part of training this autoencoder was picking the correct hyperparameters for the model, which refers to the choice of loss function, optimizer, and activation function. While intuition can certainly guide which loss functions, optimizers, and activation functions are tested out, there are multiple options for each of these hyperparameters that are plausible. The only way to determine which hyperparameter settings allow for the best convergence, and therefore most accurate reconstruction of an encoded, reduced representation is to test out different combinations.

4.7.1 Tested Loss Functions

The loss functions that were tested areaveraged version of Least Absolute Error (L1 loss) and Least Squared Error (L2 loss). L2 loss is also called Mean Squared Error Loss (MSELoss). Both of these functions are typically used for regression tasks. Since the numbers that represent scores on the different tests on the ADOS have an ordinal relationship, this problem was treated as a regression problem instead of a discrete classification problem. At the end, reconstructed values could be rounded in order to represent the integer nature of the scores for each variable on the diagnostic.

1- L1 Loss

L1loss is simple error measurement typically used for regression problems. It takes the absolute value of each error, sums them up. In PyTorch, users have the option to then average this sum on a per-sample basis. In other words, this the average absolute value difference between the network's predictions and the correct results [33]. The formula for averaged L1 loss is as follows:

$$L1 = \frac{1}{n}\sum_{i=1}^{n}\left|y^{(i)} - \hat{y}^{(i)}\right|$$

2- Mean Squared Error Loss (MSELoss)

Mean squared error, which is also commonly referred to as L2 loss, is a very simple error measurement. It takes the difference between the estimation and the correct value of each, and then squares it. These squares are all summed together, and then divided by the sample size [33]. The formula for mean squared error is as follows:

$$MSE = \frac{1}{n}\sum_{i=1}^{n}(y^{(i)} - \hat{y}^{(i)})^2$$

4.7.1.1 Reasons for Testing Both L1 & L2 Loss

At first glance, it might seem like it is unnecessary to test the performance of both L1 and L2 loss functions. Since both results were averaged out, they basically seem to be measuring the same thing. The only difference is

that mean squared error or L2 loss measures a squared version of the average absolute value error or L1 loss.

While this is true, the shape that both loss functions take for a given experiment might be different. Since each of the functions will take the form of a very complex multivariable equation, differences in function shape can make a huge difference.

For any given problem, one function might have a gradient that is easier for an optimizer to navigate than the other. Not only that, but one function might work better for one set of optimizers and activation functions, and the other function might work better for another set of optimizers and activation functions. There is no way to know beforehand which will work best, so different combinations need to be tested.

4.7.2 Tested Activation Functions

The activation functions that were tested are Rectified Linear Units (ReLU), Exponential Linear Units (ELU), Scaled Exponential Linear Units (SELU), and Softplus.

1- Rectified Linear Units (ReLU)

Rectified Linear Units or ReLU is a simple activation function that fires a neuron if its output is greater than 0, and does not activate a neuron if its value is less than 0. ReLU is the most popular activation function used by researchers in the field of deep learning. While it can

help implement a nonlinear target function that allows a network to converge upon a very difficult to reach solution to a complex problem, ReLU can be prone to backfiring in an inconvenient manner from time to time. A ReLU neuron with a large gradient might cause its weights to update in a way that permanently set that neuron's value at 0 or below, causing it to "die" and never fire again. This problem can be avoided by setting a proper learning rate that is not too high [34]. The threshold for ReLU is very simple:

$$f(x) = \max(0, x)$$

Graphically, ReLU [35] looks like this

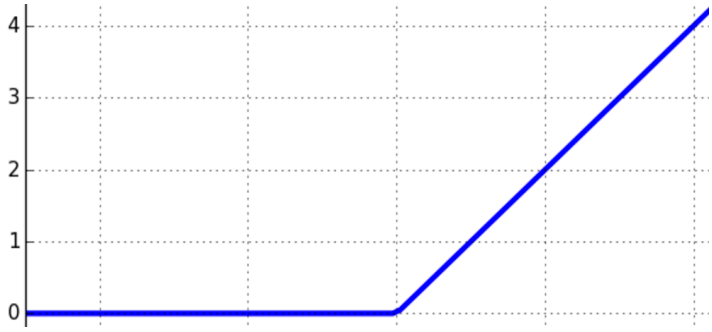

Figure 10. ReLu Activation Function

2- Exponential Linear Units (ELU)

For positive values, exponential linear units function are identical to rectified linear units. For negative values, the function has a boundary of -1 for an α value of 1.0, which the default used by PyTorch. Exponential linear units have a greater percentage of neurons fire, which ends up helping a neural network train faster [36]. The formula for exponential linear units is as follows:

$$f(x)\begin{cases} x & x \geq 0 \\ \alpha(e^x - 1) & x < 0 \end{cases}$$

Graphically, exponential linear units look like this:

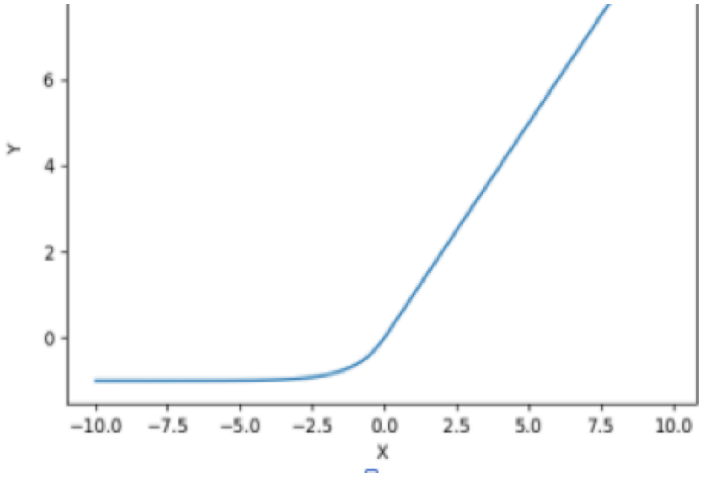

Figure 11. ELU Activation Function

3- Scaled Exponential Linear Units (SELU)

SELU works very similarly to exponential linear units (ELU). The only difference is that the exponential linear units are scaled based on two constant parameters not subject to gradients, α & λ. The default value for α is 1.6732632423543772848170429916717. The default value for λ is 1.0507009873554804934193349852946. The formula for scaled exponential linear units is as follows [37]:

$$selu(x) = \lambda \begin{cases} x & if x > 0 \\ \alpha e^x - \alpha & if x \leq 0 \end{cases}$$

Graphically, SELU looks like this:

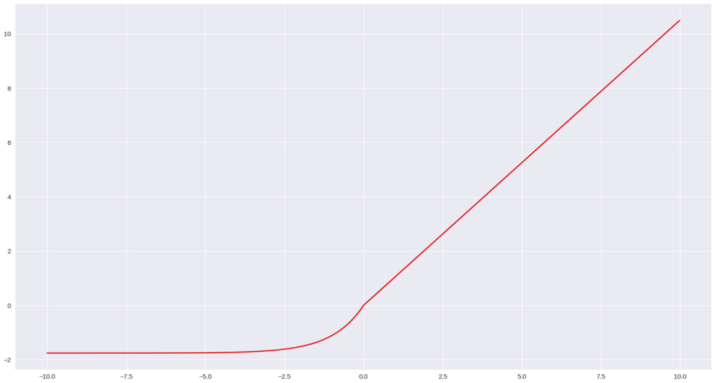

Figure 12. SELU Activation Function

4- Softplus

The softplus activation function is simply a smooth approximation of the rectified linear unit activation function (ReLU). The softplus activation function is:

$$f(x) = \ln(1 + e^x)$$

Graphically, softplus looks very similar to ReLu, but is smooth [38].

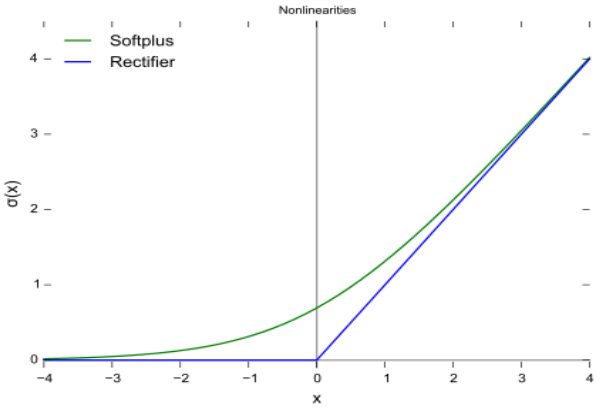

Figure13. Softplus Activation Function

4.7.3 Tested Optimizers

The optimizers that were tested are Adaptive Moment Estimation (Adam), RMSProp and Average Stochastic Gradient Descent (ASGD). In order to understand Adam and RMSProp, it is necessary to understand the optimizer Adaptive Gradient Boost.

4.7.3.1 Adaptive Gradient Boost (Adagrad)

Adagrad attempts to improve upon traditional stochastic gradient descent by normalizing updates for each parameter. After it is done, parameters with larger gradients have smaller updates, and parameters with smaller or less used gradients have larger updates [14]. The formulation of Adagrad is shown below:

$$0_{t+1,i} = 0_{t,i} - \frac{n}{\sqrt{G_{t,ii} + \epsilon}} \cdot g_{t,i}$$

The problem with Adagrad is that the cache eventually becomes too large and ceases to function properly. This process occurs because the squared gradients accumulated in the denominator, which is referred to as the cache. As the accumulated sum grows, the learning rate progressively shrinks until the algorithm learns at an infinitesimally small and computationally intractable rate [14].

1- RMSProp

The RMSProp optimization algorithm addresses the aforementioned weakness of adaptive gradient boost by decaying the size of the cache by

multiplying it by a constant fraction less than but close to 1. RMSProp also divides the learning rate for a given weight by a running average of the magnitudes of recent gradients for that weight [14].

$$cache_t = \gamma * cache_{t-1} + (1 - y) * \nabla J(\theta_t)^2$$

2- Adaptive Moment Estimation (Adam)

Adam optimizer improves RMSProp by incorporating information from past updates, by using momentum. It accumulates past squared gradients in an exponentially decaying average like RMSProp. In addition to this decaying average of squared gradients, Adam also accumulates an exponentially decaying average of previous gradients without squaring them. These two caches are running estimates of the mean and variance of past gradients, which are referred to as the first and second moments respectively. Adam then implements a bias correction to these estimates, and then uses this information to calculate new updates [14]. The Adam optimizer has the formulation:

$$m_t = \beta_1 * m_{t-1} + (1 - \beta_1) * J(\theta_t)$$

$$v_t = \beta_2 * v_{t-1} + (1 - \beta_2) * \nabla J(\theta_t)^2$$

$$\theta_t = \theta_{t-1} - \frac{\alpha * m_t}{(\sqrt{v_t})}$$

3- ASGD (Averaged Stochastic Gradient Descent)

This algorithm represents an accelerated version of stochastic gradient descent. A normal stochastic gradient descent update is performed, and then an average is calculated efficiently using a recursive formula [39].

$$\overline{w}_t = \frac{1}{t - t_0} \sum_{i=t_{0+1}}^{t} w_t$$

This average is then used to influence future updates, which can accelerate training significantly in some cases.

$$w_{t+1} = (1 - \gamma_t \lambda) w_t - \gamma_t y_t x_t l'(y_t x_t w_t)$$

$$\overline{w}_{t+1} = \overline{w}_t + \mu_t (w_{t+1} - \overline{w}_t)$$

The averaging rate is:

$$\mu_t = 1/max\{1, t - t_0\}$$

4.7.4 Batch Size, Learning Rate and Scheduler Tuning

Different batch sizes were tested throughout the training process. The batch size of a neural network refers to the number of data samples that are simultaneously sent forward through the network at one time.

During hyperparameter tuning, different initial learning rates were tested for each optimizer. The learning rate determines the size of a weight update for the optimizer. The learning rates tried altered by a factor of 10, and ranged from .01 to .00001.

An algorithm called a scheduler, which dynamically adjusts the learning rate of an optimizer once descent on the loss function has stagnated, was also tested. Results with the scheduler, for all optimizers, were significantly worse than without a scheduler. This was true with all combinations of loss and activation functions, and was true regardless of the optimizer used.

The most likely explanation for this phenomenon involves local minima within the loss function. In all likelihood, the scheduler ended up getting stuck in a suboptimal local minimum during training. Since the scheduler decreases the learning rate once learning stagnates, it is very unlikely to “escape” a local minimum during gradient descent.

4.8 Data Pipeline Prior to Training.

4.8.1 Data Preprocessing

The Autism Diagnostic Observation schedule data, covering Module 1, Module 2, Module 3, and Module 4, was supplied in the form of Excel spreadsheets with a “.xlsx” file extension. The first step in the data pipeline was to convert these “.xlsx” files to comma separated value files “.csv”. This format imports into python more cleanly.

Prior to doing this, the files were edited, as there were a small but insignificant number of samples that did not contain full ADOS data. There were also several columns in the spreadsheet that were completely unnecessary to the project. These columns included patient identification numbers and the date at which the tests were administered. Besides this, the data required very little preprocessing.

4.8.2 Moving Data into Python Environment

The programming and machine learning part of this thesis was mostly conducted within the confines of a Jupyter notebook. The data was imported into

the Jupyter notebook with a library called *Pandas*. *Pandas* is a Python open source library that provides high performance data structures and data analysis tools for the purpose of data science and machine learning projects. *Pandas* library contains a function called “read_csv”, which takes the contents of a comma separated value file and imports it into a Python programming environment.

Following this, the data in the file were quickly isolated and placed into a structure called a *Pandas* dataframe. A *Pandas* dataframe can be thought of as an analogue to an Excel spreadsheet in Python.

4.8.3 Conversion from Pandas Dataframe to Numpy Array

Numpy is a very popular Python library that allows for the computation of arrays. It is entirely possible to code a neural network from scratch using *numpy*. *Numpy* tends to be an integral part of almost every machine-learning project in Python, and supports a host of mathematical operations that are commonly used in data science and machine learning. *Numpy* arrays are stored and operated upon on CPU’s however, so for any project that requires high performance computing, *numpy* might not be sufficient.

The Pandas Dataframe needed to be converted to a *numpy* array prior to its importation into PyTorch. PyTorch tensors are generally created from *numpy* arrays, so this intermediate step was required. Also, binary mask used for the

special connections between layers was also originally created as a *numpy* array.

4.8.4 Conversion from Numpy Array to PyTorch Tensor

PyTorch tensors are commonly created from *Numpy* arrays. Both the dataset and the binary mask matrix were quickly converted from 2-dimensional *numpy* arrays to PyTorch tensors. A PyTorch tensor is conceptually equivalent to a *numpy* array.

In order for the algorithm to work, the mask and dataset had been stored in the exact same type of PyTorch tensor data structure. These tensors were first stored on the machine's CPU.

In order for the algorithm to work, the mask and dataset had to be stored in the exact same type of PyTorch tensor data structure. Furthermore, this data type had to match the data type of the weights for the network. By default, the weights of the neural network take the form of a "Float Tensor". The mask and the dataset, when imported from numpy and pandas, were initially stored as "Long Tensors". These "Long Tensors" were converted to "Float Tensors" so that the weights, mask, and data all matched. These tensors were first stored on the machine's CPU.

4.8.5 Moving PyTorch Tensors to GPU

PyTorch allows a user to run algorithms on GPU rather than CPU for the sake of efficient computing. The next step in the pipeline was to convert the

PyTorch CPU tensors currently in use to PyTorch GPU tensors, which effectively moves the data storage from the CPU to GPU.

PyTorch take advantage of NVIDIA's CUDA library for computations run on NVIDIA GPU, so the PyTorch tensors were redefined as a specialized tensor optimized for CUDA computations. These steps were administered for both the mask and for the dataset.

4.8.6 Wrapping GPU Tensors in PyTorch Variables

PyTorch features the convention of wrapping tensor data structures into objects called Variables prior to using them in a model. These Variable objects have an attribute called ".data" that refers to the tensor held within the Variable.

Once the data and the mask were wrapped in Variables while stored on the GPU, the model was ready to be trained.

CHAPTER FIVE

MODEL TRAINING

5.1 Introduction

This section describes the training process for all autoencoders used in this thesis. This information includes the hyperparameters used, training procedures for avoiding overfitting, the logic behind these procedures, the duration of training, and the implementation of training within PyTorch.

Once the correct configuration of hyperparameters had been selected for the autoencoders, each module was ready to be trained. The GPU used for training these models was an Nvidia GTX 870, which allows for accelerated computations using NVIDIA's CUDA framework integrated into PyTorch. Neural networks train significantly faster on GPU, so training these models on GPU's allowed for a greater amount of experimentation.

5.2 Final Hyperparameters Used

With the different combination of the loss, activation and optimizer tested, L1 loss function, SELU activation function and Adam optimizer yielded the best results. This combination was used for all autoencoder architectures in all modules.

5.2.1 L1 Loss

L1 loss function as mentioned previously measures average absolute value between the networks predictions and the correct result then sum them up. In PyTorch, users have the option to then average this sum on a per-sample basis. In other words, this represents the average absolute value difference between the network's predictions and the correct results [29]. The formula for averaged L1 loss is as follows:

$$L1 = \frac{1}{n}\sum_{i=1}^{n}\left|y^{(i)} - \hat{y}^{(i)}\right|$$

In this case, L1's gradient took a shape that was easier for the Adam optimizer to descend upon.

5.2.2 SELU

SELU as mentioned previously the exponential linear units are scaled based on two constant parameters not subject to gradients, α & λ [33]. SELU do not transform positive neuron outputs, and simply bound negative neuron outputs at -1 with a biased exponential transformation. As will be discussed later, it is unlikely that scaled exponential units transformed weighted outputs to a significant degree. For whatever reason, scaled exponential linear units worked better than competing activation functions. The formula for scaled exponential linear units is as follows:

$$selu(x) = \lambda \begin{cases} x & if x > 0 \\ \alpha e^{x} - \alpha & if x \leq 0 \end{cases}$$

4.2.3 Adam

Adam as mentioned previously accumulates past squared gradients in an exponentially decaying average. In addition to this decaying average of squared gradients, Adam also accumulates an exponentially decaying average of previous gradients without squaring them. These two caches are running estimates of the mean and variance of past gradients, which are referred to as the first and second moments respectively. Adam then implements a bias correction to these estimates, and then uses this information to calculate new updates [17]. The Adam optimizer has the formulation:

$$m_t = \beta_1 * m_{t-1} + (1 - \beta_1) * J(\theta_t)$$

$$v_t = \beta_2 * v_{t-1} + (1 - \beta_2) * \nabla J(\theta_t)^2$$

$$\theta_t = \theta_{t-1} - \frac{\alpha * m_t}{(\sqrt{v_t})}$$

It adapts updates on a per-parameter basis, and is able to incorporate a concept of momentum as well. These traits, in all likelihood, decreased the probability of the Adam optimizer getting stuck in a suboptimal local minimum.

4.2.4 Final Batch Size, Learning Rate and Scheduler

As mentioned earlier, different batch sizes and learning rate were tested. The best final set of autoencoders was batch of size 10 and a learning rate of size ($1.0*10^{-4}$) or .0001 across all architecture modules. Implementing a learning rate scheduler led to worse performance across the board in every architecture, so the scheduler was completely omitted from training.

5.3 Overfitting

Overfitting is when a model's target function maps inputs to outputs in a way that too closely matches the training data. When this happens, the model learns a pattern that is overly specific, and matches the training data, but would fail to regularize and apply to other similar data sets. Overfitting in neural networks is often mitigated by the implementation of a technique called dropout.

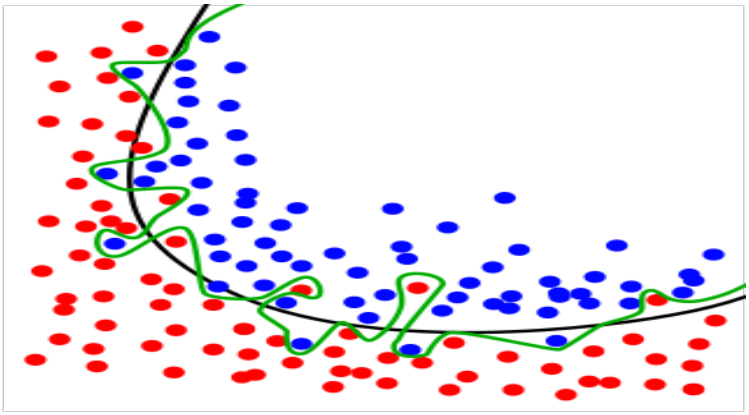

Figure 14. Overfitting [40]

4.3.1 Dropout

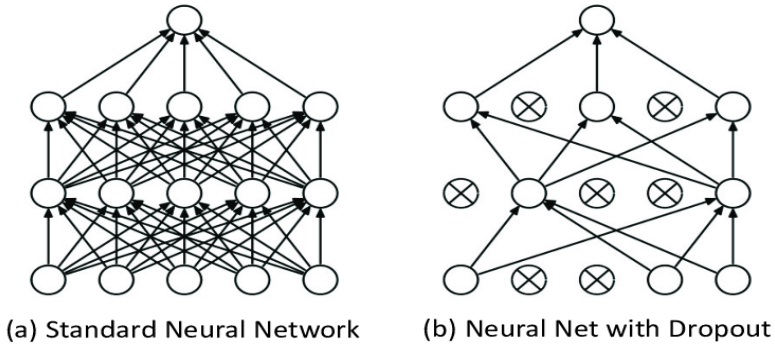

Figure 15. Dropout [41]

Researchers who train neural networks typically use dropout to avoid overfitting. Dropout is a procedure by which certain numbers of neurons in each layer are removed from any given forward pass [42]. The neurons removed will vary on each forward pass. The idea behind this is that the model is forced to learn a target function despite different neurons being deactivated at different times. Doing this should help prevent the neural network from developing a target function that is overly specific to the dataset. Dropout, however, was not used in this project for the reason mentioned below.

4.3.1.1 Reason not Using Dropout

Since the autoencoders employed in this project already had a large number of neurons removed from training due to the specialized connections between layers enforced by the binary mask matrix, dropout seemed like it would be less effective than normal. Simply dropout removes neurons, and the project's design also removes neurons, and there seemed to be a degree of redundancy there.

4.3.2 K-Fold Cross Validation

K-fold cross validation is a technique used to prevent overfitting. In k-fold cross validation the data set is randomly partitioned into a training set and a validation set [43]. The diagram below shows k-fold cross validation.

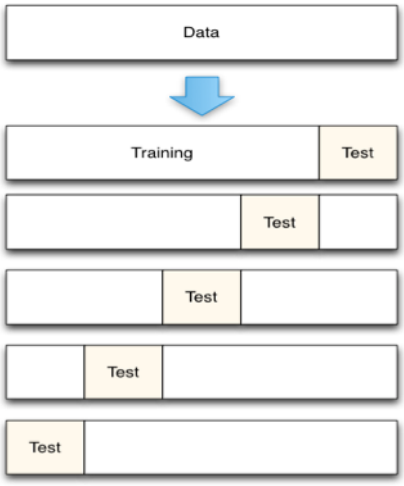

Figure 16. K-Fold Cross Validation [43]

K-fold cross validation in this experiment was implemented as follows. The data set was shuffled and randomly split into a training set and a test set. 90% of the data was used for training, and 10% for a test. The model was trained using the training data for 100,000 epochs, and then tested on the remaining test data. This represents a single fold in k-fold cross validation. Afterwards, entire data set was shuffled and randomly split again into a different training and test set of the same portions. Another fold of training and testing was carried out, followed by another random shuffle and split, until 10 folds of cross validation had been executed. This procedure theoretically prevents the model from approximating a target function that becomes overly reliant on a certain subsection of the dataset, thereby acting as a bulwark against overfitting.

5.3.3 Code for K-Fold Cross Validation and Model Training

Because PyTorch is very tightly integrated with the Python language, it was possible to implement k-fold cross validation by using traditional Python

control flow methods. The 10 splits of cross validation were written in the form of a Python *for* loop of 10 iterations. In each loop, the dataset was randomly split with a 9:1 training to validation ratio. Within each split, the model was trained for 100,00 epochs. The training was also represented as a *for* loop within the cross-validation *for* loop. The training loop consisted of 100,000 iterations.

5.4 Training

Each autoencoder was trained for 1,000,000 epochs consisting of 10 splits of 100,000 epochs for k-fold cross validation. Since the datasets were small and PyTorch is exceptionally efficient, the models were able to converge upon local minima very easily within this time.

For each autoencoder structure in each module, training was conducted 10 times. The results of each training session were saved, and the final weights for each structure represented an average of these 10 iterations.

5.4.1 Training Time

Each architecture took roughly 1 hour to train. This extrapolates to roughly 160 hours of total training time over the course of the experiment for all iterations of autoencoders on different modules.

5.4 Data Pipeline After Training

5.4.1 Pipeline for Reconstructed Data Set and Target

5.4.1.1 Moving Tensor to CPU

The first step in the pipeline, following training of the model, was to remove the data held in the Variable object representing the reconstructed ADOS dataset and the target. The next step was to convert the GPU tensor for the data into a CPU tensor, since the only purpose of using the GPU was training the model. These two steps were conducted in a single line of code for the reconstruction and target.

5.4.1.2 Convert PyTorch CPU Tensor to Numpy Array

Since the end goal of the pipeline was to convert the reconstructed data into a csv, similar to the original data, the Pytorch tensor needed to be converted to a Numpy array as an intermediate step between PyTorch and Pandas.

5.4.1.3 Convert Numpy Array to Pandas Data Frame

The next step in the pipeline was to convert the Numpy array into a Pandas data frame. The column names of the dataset were specified when creating the dataframe because this information was lost during training, as the model did not include column labels with the input.

5.4.1.4 Convert Pandas Dataframe to Comma Separated Value File

The final step in the reconstruction and target pipeline was to convert a pandas data frame into a comma separated value file so that it could be compared to the input.

5.4.2 Pipeline for Weights

The parameters of the model in PyTorch are stored in an iterable object referred to as “model.parameters”. The parameters object of the model has an attribute referred to as “param.data”.

To remove the weights from this object, a *for* loop was constructed to iterate through “model.parameters” and convert the data within into a PyTorch tensor.

From there, the weights followed the exact same pipeline as the reconstructed dataset did.

CHAPTER SIX

MODEL VALIDATION

6.1 Introduction

Validating a model involves insuring that the model can reliably and accurately achieve its purpose on relevant datasets. In this chapter, the accuracy of autoencoders at reconstructing their inputs will be evaluated. Since the purpose of an autoencoder is to accurately reconstruct its input as its target, validation for this project involved testing if the autoencoders used were actually able to accurately reconstruct their inputs. Accuracy was measured for each training iteration of autoencoders used in this project. Average accuracies are calculated for each combination of autoencoder architecture and module. A table of all autoencoder training iterations and their respective reconstruction accuracies can be found in Appendix D.

6.2 Validation Method

Validation was conducted by testing how accurately an autoencoder was able to reconstruct its input. Reconstructing an input from a smaller hidden layer effectively represents an autoencoders ability to decode its hidden layer and recover as much information about its input as possible. All analysis of variables that go into a reduced representation of the ADOS is only relevant if the

autoencoder can reliably reconstruct the original higher-dimensional sample from that reduced representation.

6.2.1.1 Compare Output with Target

As mentioned previously, in the model the data was split into 90 percent training and 10 percent validation. Following this division, the model trained normally for a certain number of epochs.

After training was completed for this partition, the dataset is then reshuffled and divided into a different random partition of 90/10. The model is then trained again, and then shuffled and randomly divided again, for an arbitrary number of splits.

The final outputs of the autoencoder represent reconstructed versions of the training data and the test data. Collectively, all samples from the original dataset are in the output, the only difference is that order is switched. For the sake of examining the autoencoder output, the training set reconstructions were compared to the training set splits, since these represent the overwhelming majority of the input data. The data for every individual patient remains completely unchanged, so comparing the reconstruction to the shuffled data set is a completely valid method for evaluating the reconstruction performance of the autoencoder. However, since the order of the patients has been changed, the reconstruction compared to the original data set as supplied by the AGRE in its original patient order.

K-fold cross validation was conducted to attempt to limit the potential for overfitting by this model.

6.2.1.2 Calculating the Accuracy

Since the output was treated as a regression problem, all values in the output had to be rounded to the nearest integer prior to comparison with the input. After rounding, overlapping comma separated value files were compared, and all discrepancies highlighted. The number of discrepancies represents the number of observations that the autoencoder failed to accurately reconstruct. By dividing the number of discrepancies by the total number of observations, the percentage of wrong observations was calculated. Subtracting this percentage from 1 gave an accuracy percentage for the autoencoder.

6.2.1.3 Average the Accuracy

Accuracy numbers were calculated for all 10 autoencoders for a single architecture and module. To determine the reconstruction accuracy of a given autoencoder, the number of correct values divided by total values was calculated for each training session. After accuracy percentages were calculated for all 10 training versions of a single architecture and module combination, those accuracies were averaged to estimate the aggregate average accuracy of a given architecture in reconstructing a module.

6.3 Autoencoder Reconstruction Accuracy

6.3.1 Module 1 Autoencoder Reconstruction Accuracy

The diagram below shows the average accuracy across Module 1 architectures.

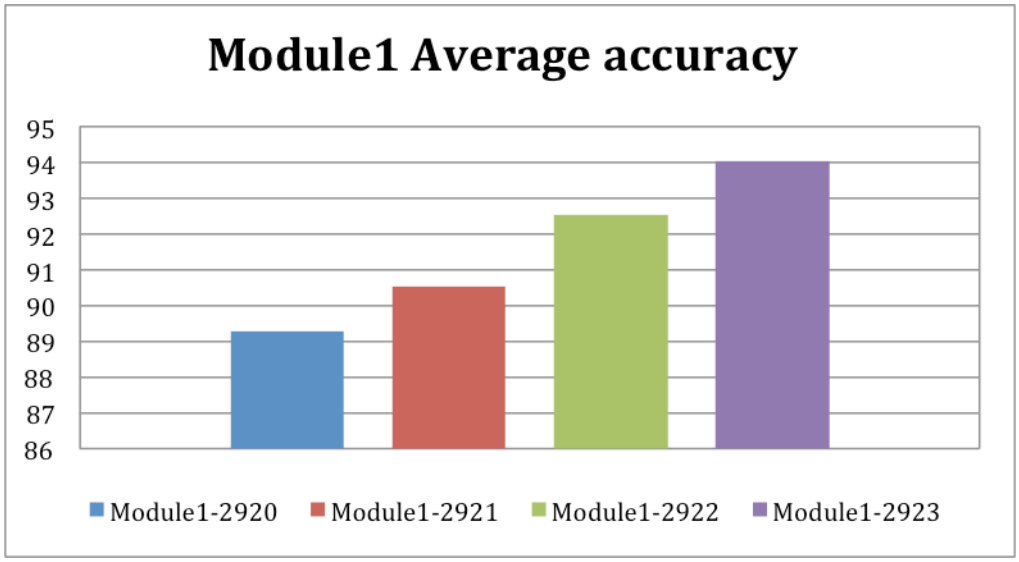

Figure 17. Average Accuracy Across Module 1

All autoencoders tested ended up with accurate reconstructions. Within Module 1, the autoencoder that reduced the 29-variable diagnostic to 20 variables ended up reconstructing its inputs with 89.3% accuracy. This number, and each of the following average accuracy measures, describes the average accuracy of 10 identically designed and trained autoencoders. The least accurate of the 10 autoencoders reconstructed its input with 87.56% accuracy, and the most accurate reconstructed its input with 90% accuracy.

The autoencoder architecture that reduced the 29-variable Module 1 to 21 variables had an average accuracy of 90.5%. The least accurate iteration scored at 89.35% accuracy, and most accurate iteration had accuracy of 91.74%.

The autoencoder architecture that reduced the 29-variable Module 1 to 22 variables had an average accuracy of 92.5%. The least accurate iteration scored at 91.54% accuracy, and most accurate iteration had accuracy of 93.36%.

The autoencoder architecture that reduced the 29-variable Module 1 to 23 variables had an average accuracy of 94%. The least accurate iteration scored at 93.35% accuracy, and most accurate iteration had accuracy of 94.53%.

As one might expect, Module 1 autoencoders with larger hidden layers were more accurate at reconstructing than autoencoder architectures with smaller hidden layers.

6.3.2 Module 2 Autoencoder Reconstruction Accuracy

The diagram below shows the average accuracy across Module 2 architecture**.**

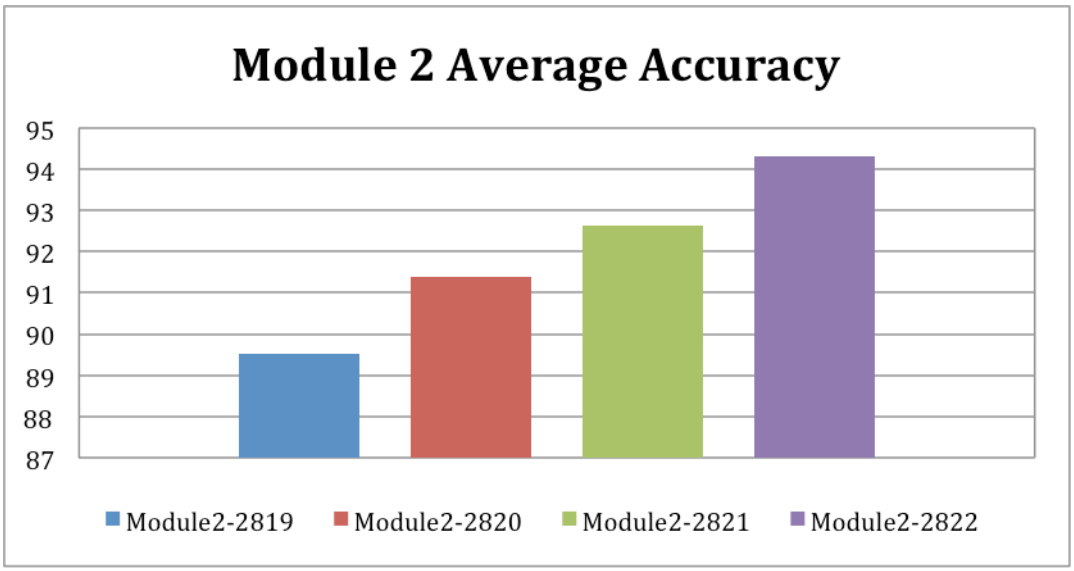

Figure 18. Average Accuracy Across Module 2

On Module 1, the autoencoder that reduced the 28-variable diagnostic to 19 variables ended up reconstructing its inputs with 90.5% accuracy. The least accurate of the 10 autoencoders reconstructed its input with 88.15% accuracy, and the most accurate reconstructed its input with 91.12% accuracy.

The autoencoder architecture that reduced the 28-variable Module 2 to 21 variables had an average accuracy of 91.4%. The least accurate iteration scored at 90.97% accuracy, and most accurate iteration had accuracy of 91.86%.

The autoencoder architecture that reduced the 28-variable Module 2 to 22 variables had an average accuracy of 92.6%. The least accurate iteration scored at 92.03% accuracy, and most accurate iteration had accuracy of 93.59%.

The autoencoder architecture that reduced the 29-variable Module 2 to 23 variables had an average accuracy of 94.3%. The least accurate iteration scored at 92.22% accuracy, and most accurate iteration had accuracy of 95.08%.

Module 2 autoencoders showed decreased accuracy with smaller hidden layers, as is expected.

6.3.3 Module 3 Autoencoder Reconstruction Accuracy

The diagram below shows the average accuracy across Module 3 architecture.

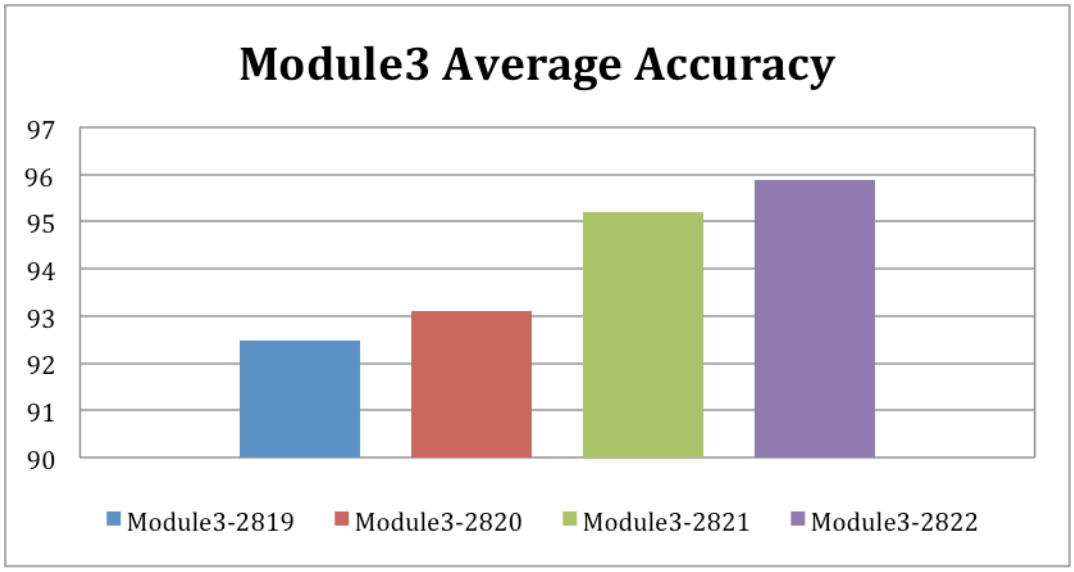

Figure 19. Average Accuracy Across Module 3

On Module 3, the autoencoder that reduced the 28-variable diagnostic to 19 variables ended up reconstructing its inputs with 92.5% accuracy. The least accurate of the 10 autoencoders reconstructed its input with 91.60% accuracy, and the most accurate reconstructed its input with 93.37% accuracy.

The autoencoder architecture that reduced the 28-variable Module 3 to 20 variables had an average accuracy of 93.1%. The least accurate iteration scored at 92.48% accuracy, and most accurate iteration had accuracy of 93.67%.

The autoencoder architecture that reduced the 28-variable Module 3 to 21 variables had an average accuracy of 95.2%. The least accurate iteration scored at 94.23% accuracy, and most accurate iteration had accuracy of 96.09%.

The autoencoder architecture that reduced the 29-variable Module 3 to 22 variables had an average accuracy of 95.9%. The least accurate iteration scored at 95.07% accuracy, and most accurate iteration had accuracy of 96.82%.

Module 3 autoencoders showed decreased accuracy with smaller hidden layers, as is expected.

6.3.4 Module 4 Autoencoder Reconstruction Accuracy

The diagram below shows the average accuracy across Module 3 architecture.

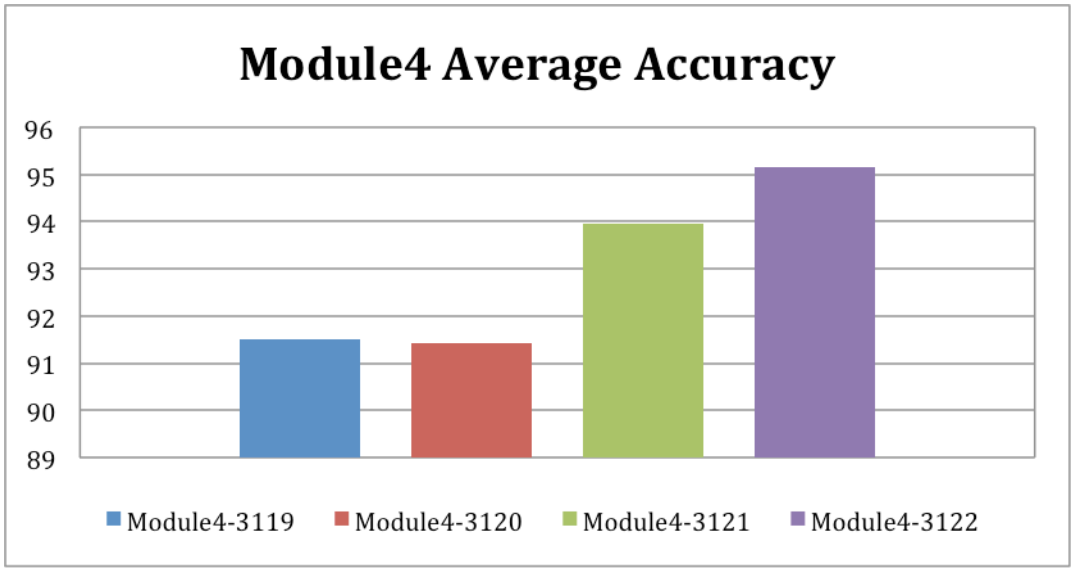

Figure 20. Average Accuracy Across Module 4

On Module 4, the autoencoder that reduced the 31-variable diagnostic to 19 variables ended up reconstructing its inputs with 91.5% accuracy. The least

accurate of the 10 autoencoders reconstructed its input with 90.93% accuracy, and the most accurate reconstructed its input with 91.15% accuracy.

The autoencoder architecture that reduced the 31-variable Module 4 to 20 variables had an average accuracy of 91.4%. The least accurate iteration scored at 91.00% accuracy, and most accurate iteration had accuracy of 92.21%.

The autoencoder architecture that reduced the 31-variable Module 4 to 21 variables had an average accuracy of 94%. The least accurate iteration scored at 93.52% accuracy, and most accurate iteration had accuracy of 94.31%.

The autoencoder architecture that reduced the 31-variable Module 4 to 22 variables had an average accuracy of 95.1%. The least accurate iteration scored at 94.48% accuracy, and most accurate iteration had accuracy of 95.82%.

Module 4 autoencoders mostly showed decreased accuracy with smaller hidden layers, with one exception. The 19-variable hidden layer actually had an accuracy that was on average 0.1% higher than the 20-variable hidden layer. With the exception of this discrepancy, the trend held true throughout all autoencoders.

CHAPTER SEVEN

MODEL ANALYSIS

7.1 Introduction

This section explores the weights of autoencoders to extract all possible insights regarding the focal points of a reduced diagnostic. The lowest dimensional reconstruction is evaluated for each module. Additionally, weights are examined across all architectures within a module, and across all modules to see if there are any consistent overarching trends.

7.2 Analysis Method

7.2.1 Comma Separated Value File

After Convert Pandas data frame to csv file, weights can be accessed in Excel. The encoder weights pulled from each autoencoder represent the weights used in the final epoch of training, prior to being element-wise multiplied with the binary mask matrix. Therefore, a large number of the weights in the comma separated value file were not used. It is simple to identify these weights based on their rows and columns, and delete them. Weights that were removed by the mask on the final forward pass were deleted prior to weight analysis for the purpose of clarity.

7.2.2 Averaging Weights

After 10 autoencoders for each architecture and module were trained, the weights from each autoencoder were converted to absolute values. The absolute value of a variable's weights determines its impact in the reduced diagnostic, so whether a weight was positive or negative was irrelevant in terms of its impact. After conversion to absolute values, the weights for all 10 identical autoencoders were averaged before analysis.

7.2.3 Reduced Diagnostic Analysis

Since all autoencoders tested demonstrated a satisfactory level of accuracy, the following analysis focuses on the autoencoder with the lowest dimensional hidden layer for each module. Therefor, a reduced diagnostic size of 20 variables for Module 1, and 19 variables for Module 2, Module 3, and Module 4. The weight data for the other architectures and modules can be found in Appendix E.

7.2.4 Explanation of Graphs for Nodes

The following pie charts show the relative strength of connections between nodes in the input layer and nodes in the hidden layer. With the type of autoencoders employed in this project, nodes corresponding to original diagnostic variables influence, through weights, nodes corresponding to condensed variables in the reduced diagnostic. Each of the following pie charts represents a single node in the reduced section and shows the relative extent to

which different variables in the original diagnostic influenced the node through their respective weights.

7.2.5 Explanation of Graphs for Sections

The following bar chart compares the impact of the weights of each variable in terms of impact across an entire reduced diagnostic section. These numbers are simply calculated by summing the weights of a single variable in every question in its relevant section. These bar graphs display which variables had the greatest impact on the reduced diagnostic shown here, and allows for their comparison.

7.2.6 Explanation for Correlations and Correlational Graphs

The following graphs show correlational relationships between the weights of variables in each section of the autoencoder. Values approaching 1 show a near perfect positive correlation, values approaching -1 show a near perfect inverse correlation. Variable pairs with values of 0 demonstrate no discernable correlational relationship. When two variables correlate in the positive direction, it means that increased presence of one variable generally accompanies increased presence of another. For this experiment, correlations with strength of 0.7 or greater were treated as strong positive relationships, and correlations greater than 0.9 were treated as almost perfectly correlated.

7.2.7 Meaning of Weights

The weight composition of a node in the hidden layer shows the extent to which variables in the input layer affected that node. Since weights represent coefficients for different inputs, weights with the highest absolute values represent a greater strength of connection between input nodes and hidden layer nodes. Absolute values close to zero represent minimal influence between nodes. Therefore, by examining the weight composition of each hidden layer node, in terms of the relative weight strength of input variables, it is possible to examine the conceptual makeup of each node in the hidden layer. On a section-by-section basis, seeing which input variables were the most represented and least represented in the reduced diagnostic can give insights as to how ADOS might be reduced into a shorter, viable diagnostic.

7.3 Module 1 Analysis

The diagram below shows the Module 1 Autoencoder with a hidden layer of size 20.

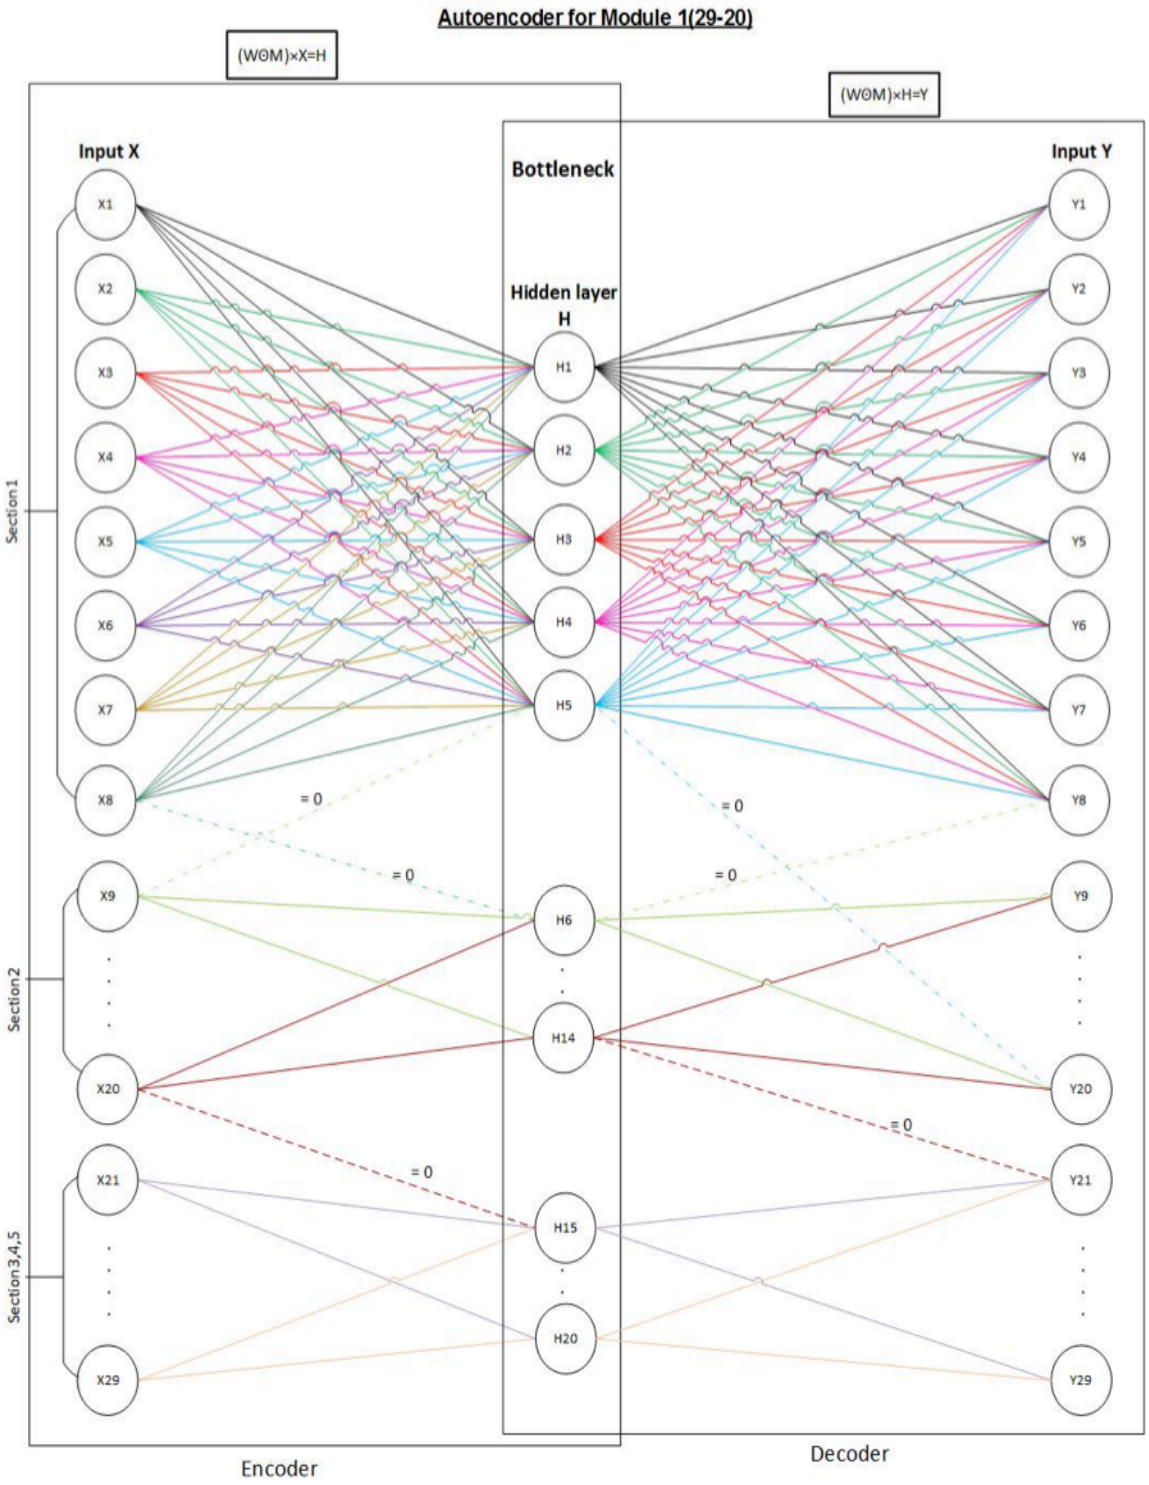

Figure 21. Module 1 Autoencoder with a Hidden Layer of Size 20

7.3.1 Module 1 Section 1 Analysis

The autoencoder reduced the first section of Module 1 from 8 variables to 5 variable sections. Section 1 subject is Language and Communication. The 8 variables in this section are Overall Level of Non-Echoed Spoken Language (OLANG), Frequency of Spontaneous Vocalization Directed to Others (FVOC), Intonation of Vocalizations or Verbalizations (INTON), Immediate Echolalia (IECHO), Stereotyped/Idiosyncratic Use of Words or Phrases (STEREO), Use of Another's Body (UOTHER), Pointing (POINT), and Gestures (GEST). The diagrams below show the weights of the reduced diagnostic of this section.

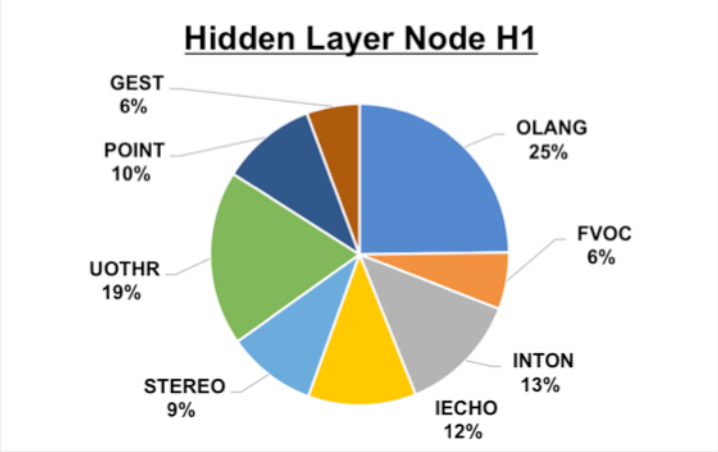

Figure 22. Relative Weights Impacts Node H1 – Module 1

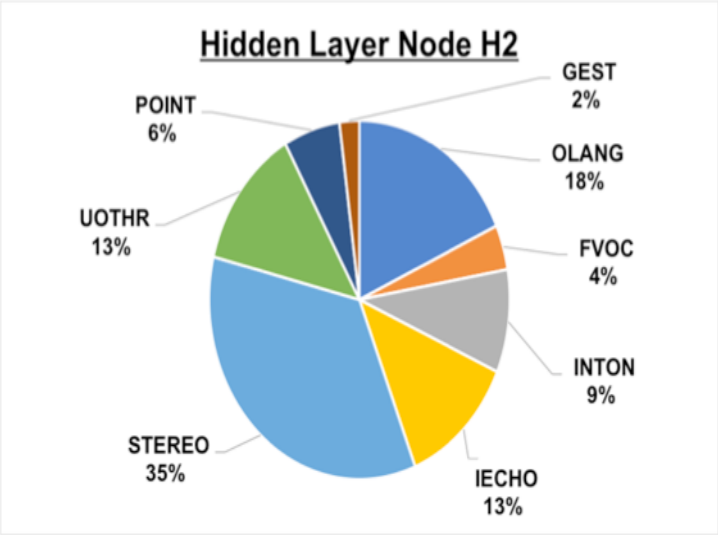

Figure 23. Relative Weights Impacts Node H2 – Module 1

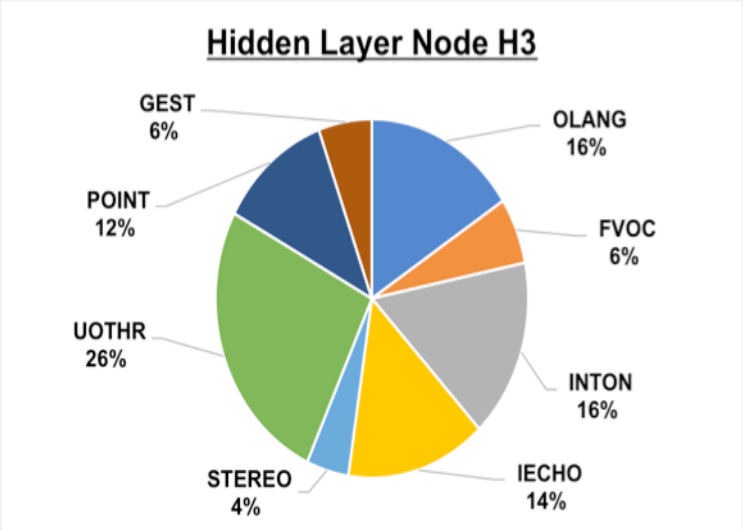

Figure 24. Relative Weights Impacts Node H3 – Module 1

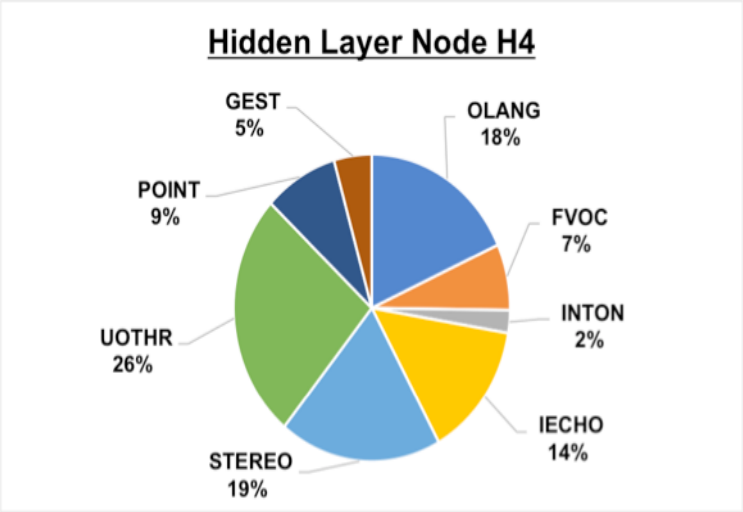

Figure 25. Relative Weights Impacts Node H4 – Module 1

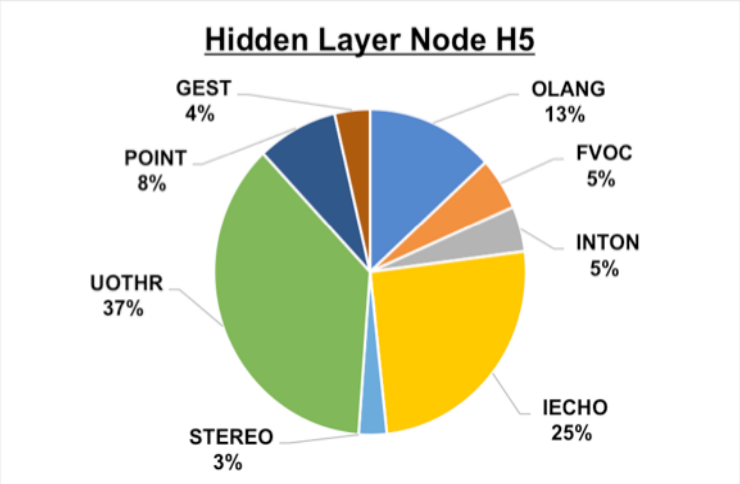

Figure 26. Relative Weights Impacts Node H5 – Module 1

The variables with the least representation in the reduced diagnostic are POINT, FVOC, and GEST. UOTHER" has the greatest presence by a significant margin. OLANG, IECHO and STEREO also had strong presences in the reduced diagnostic.

Variables with strong weights can potentially serve as focal points for a reduced ADOS with a 20-variable Module 1. POINT and GEST might be redundant variables, given there near perfect correlations. It should be noted that the variables with the smallest weight presences in this section still had significant absolute values, especially in comparison to weights analyzed in other sections and other modules. It is difficult to advocate completely disregarding any variables in the first section, but there might exist possibilities for more concise observation variable lists.

7.3.1.1 Correlation Between Variables

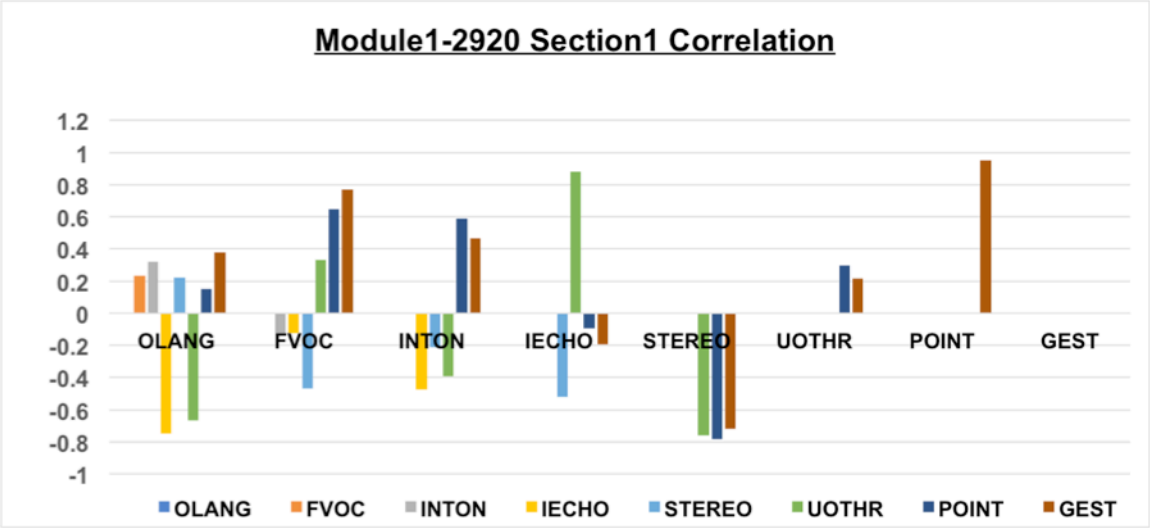

Figure 27. Weights Correlations – Module 1 Section 1

Within the reduced diagnostic nodes, the weights of IECHO and UOTHER almost perfectly correlate in their presence. Likewise, the weights of POINT and GEST have a correlation of almost 1.

7.3.2 Module 1 Section 2 Analysis

Section 2 of Module 1 of the ADOS involves the subject of Reciprocal Social Interaction. The autoencoder reduced this section from 12 variables to 9 variables. The original 12 variables were Unusual Eye Contact (UEYE), Responsive Social Smile (SSMILE), Facial Expressions Directed to Others (FACEO), Integration of Gaze (GZSOV) and Other Behaviors During Social Overtures, Shared Enjoyment in Interaction (SHRNJ), Response to Name (RNAME), Requesting (REQ), Giving (GIVE), Showing (SHOW), Spontaneous Initiation of Joint Attention (SIJNT), Response to Joint Attention (RJNT), and Quality of Social Overtures (QSOV). The diagrams below shows the weights of the reduced diagnostic of this section.

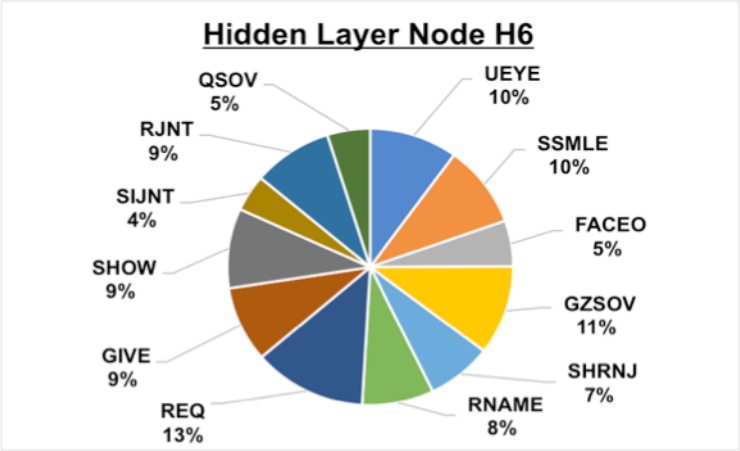

Figure 28. Relative Weights Impacts Node H6 – Module 1

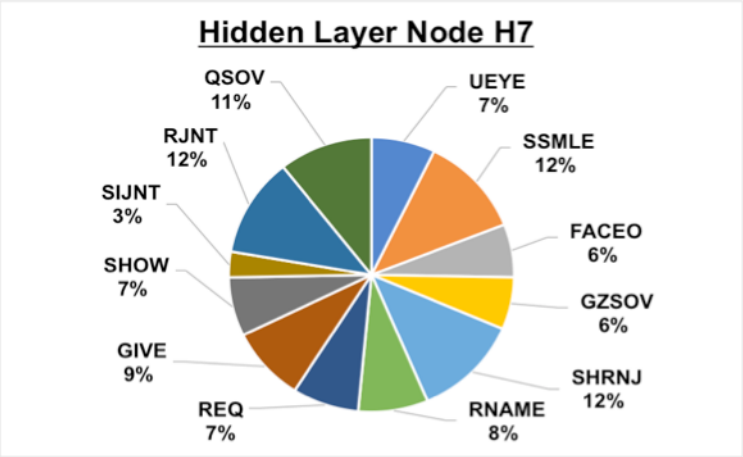

Figure 29. Relative Weights Impacts Node H7 – Module 1

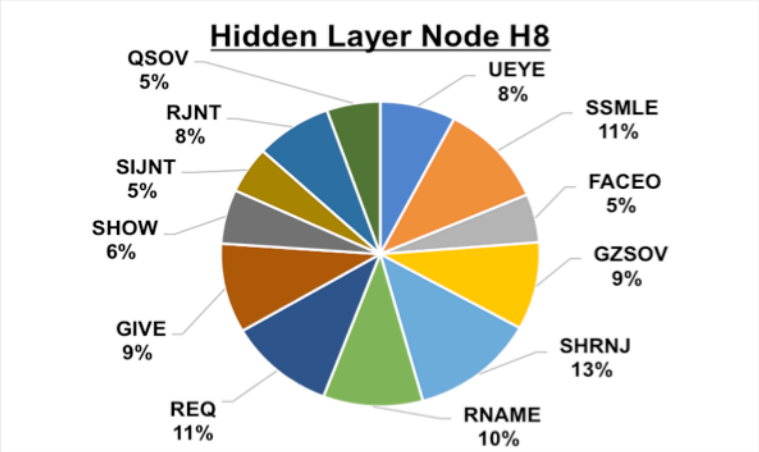

Figure 30. Relative Weights Impacts Node H8 – Module 1

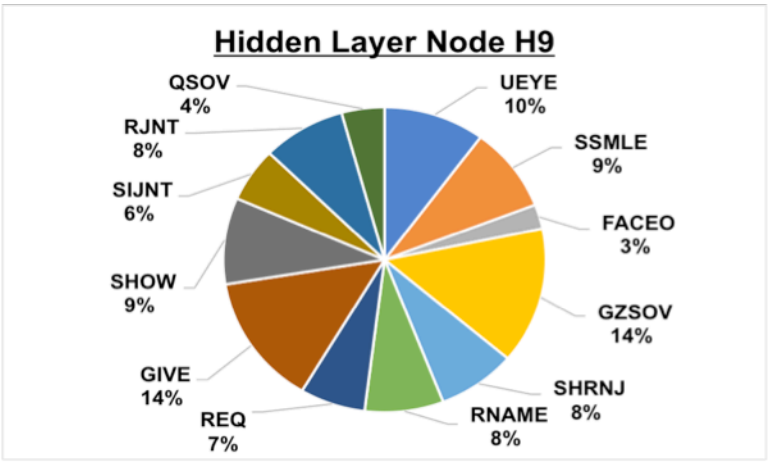

Figure 31. Relative Weights Impacts Node H9 – Module 1

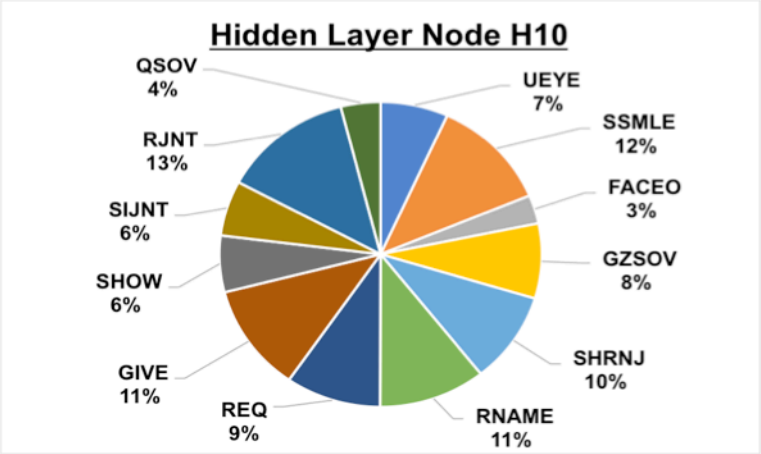

Figure 32. Relative Weights Impacts Node H10 – Module 1

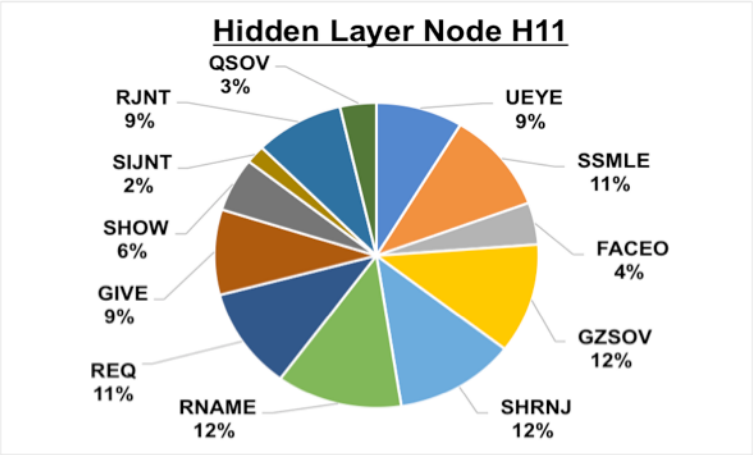

Figure 33. Relative Weights Impacts Node H11 – Module 1

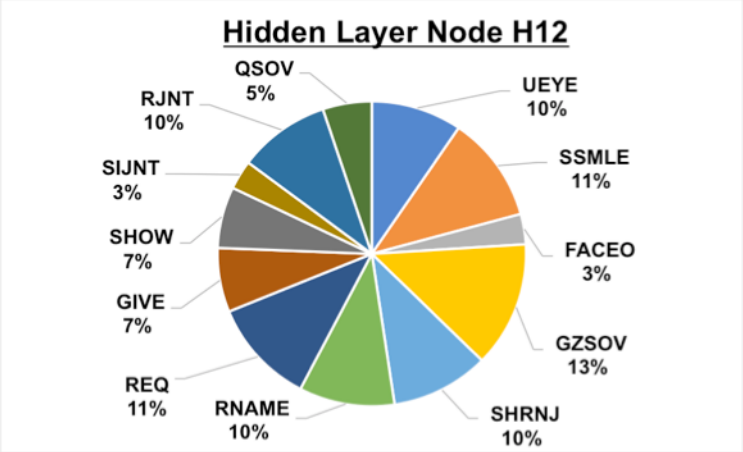

Figure 34. Relative Weights Impacts Node H12 – Module 1

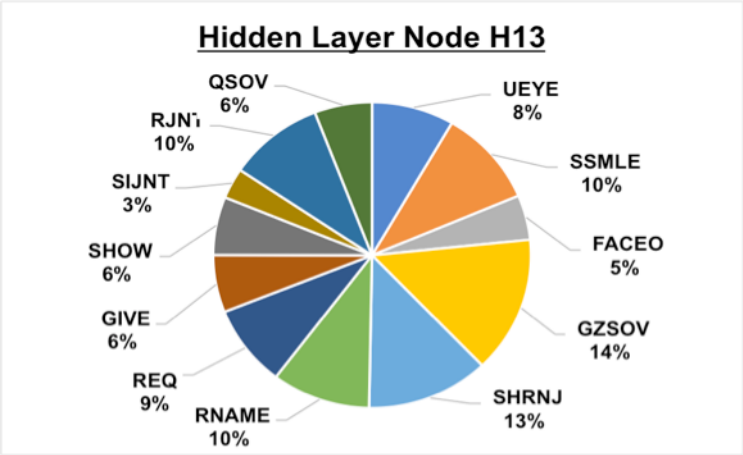

Figure 35. Relative Weights Impacts Node H13 – Module 1

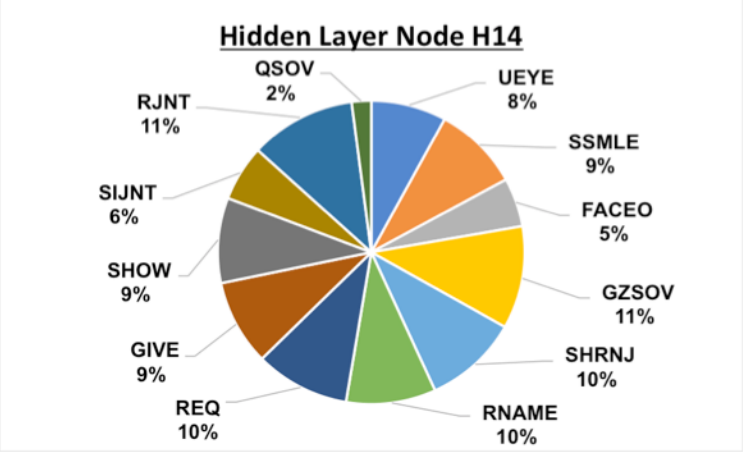

Figure 36. Relative Weights Impacts Node H14 – Module 1

In this section, none of the weights were negligible, but there did exist a clear hierarchy in variable importance. GZSOV, SSMILE and SHRNJ were the three most important variables by a significant margin. RJNT, REQ, RNAME, and GIVE formed the next tier of importance. UEYE and SHOW were of middling importance. SIJNT, FACEO, and QSOV were the three least represented

variables by a significant margin. Again, this information might have utility in identifying focal points for condensed observations.

7.3.2.1 Correlation Between Variables

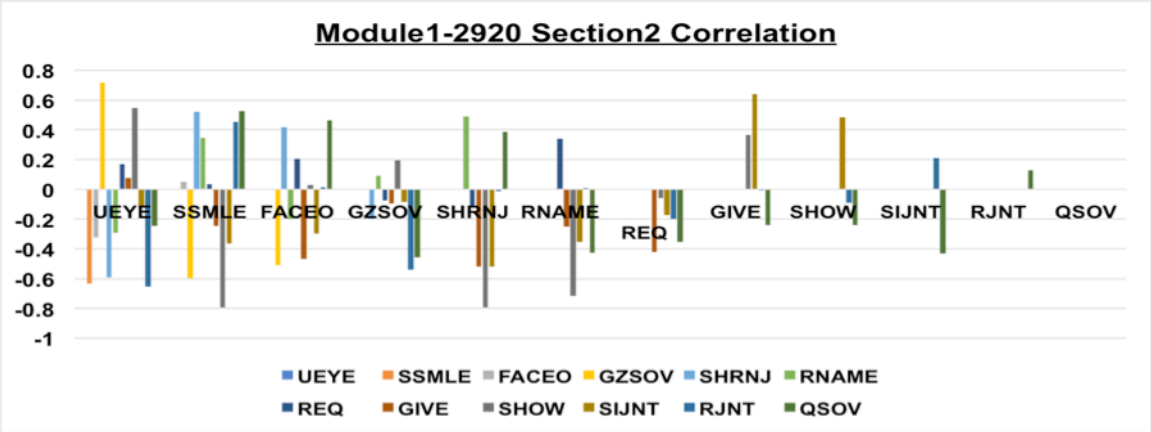

Figure 37. Weights Correlations – Module 1 Section 2

Correlations of 0.5 are considered weak according to conventional statistics.

7.3.3 Module 1 Section 3 Analysis

The third section of the reduced Module 1 autoencoder involved reducing 9 original ADOS variables into 6 new ones. The 9 original variables spanned the subjects of Play, Stereotyped Behaviors/Restricted Interests, and Other Abnormal Behaviors. The original variables were Functional Play with Objects (FPLAY), Imagination/Creativity (IMGCR), Unusual Sensory Interest in Play Material/Person (USENS), Hand and Finger and Other Complex Mannerisms (OMAN), Self-Injurious Behavior (SELFINJ), Unusually Repetitive Interests or Stereotyped Behaviors (URBEH), Overactivity (ACTIVE), Tantrums, Aggression,

Negative or Disruptive Behavior (AGG), and Anxiety (ANXTY). The diagrams below shows the weights of the reduced diagnostic of this section.

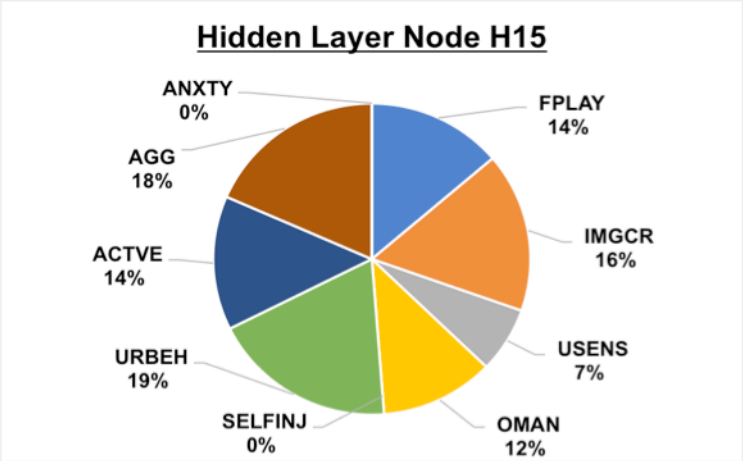

Figure 38. Relative Weights Impacts Node H15 – Module 1

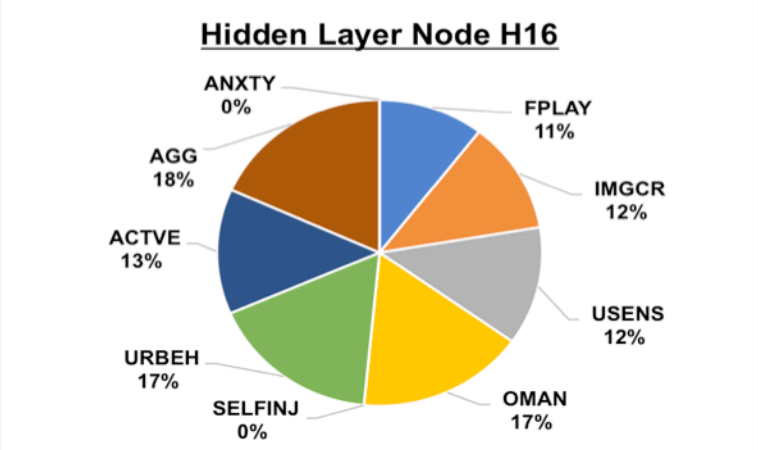

Figure 39. Relative Weights Impacts Node H16 – Module 1

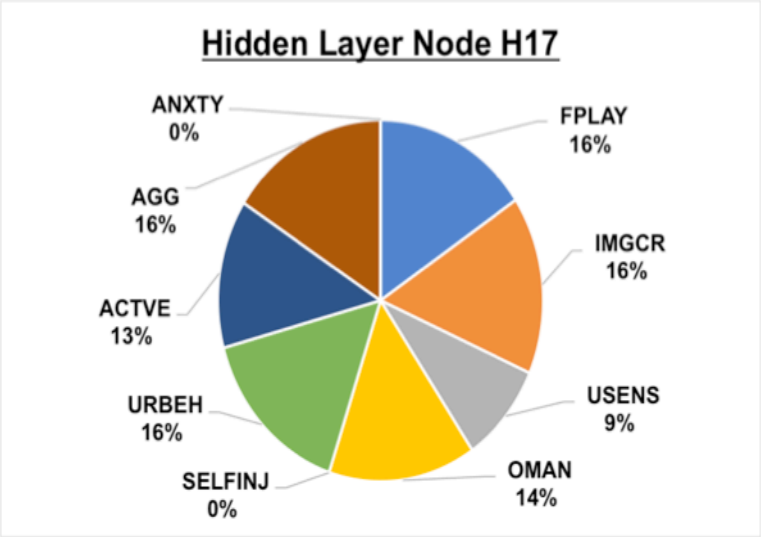

Figure 40. Relative Weights Impacts Node H17 – Module 1

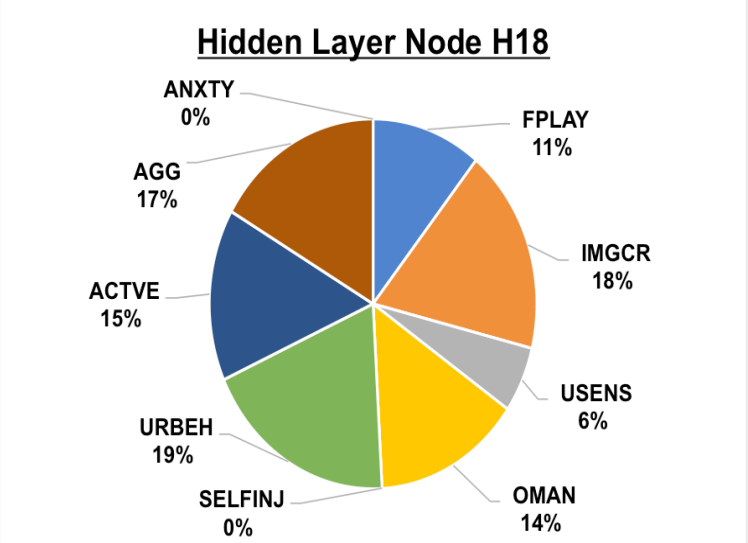

Figure 41. Relative Weights Impacts Node H18 – Module 1

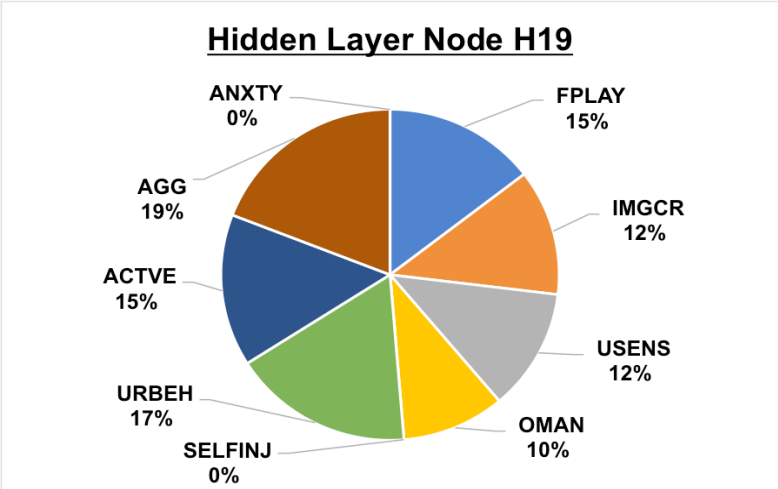

Figure 42. Relative Weights Impacts Node H19 – Module 1

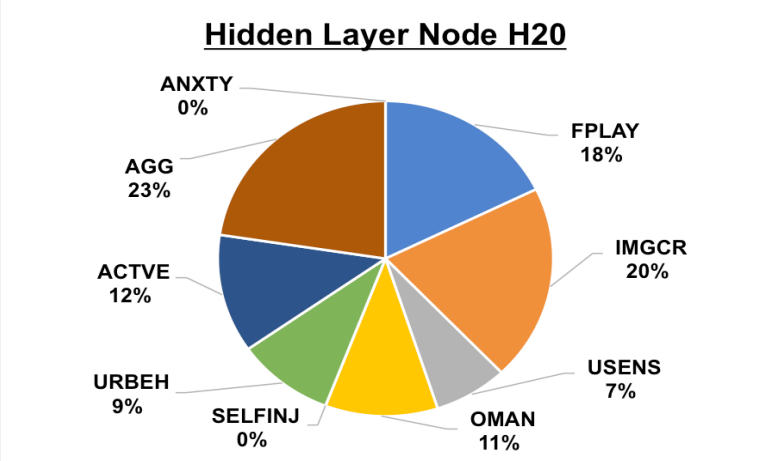

Figure 43. Relative Weights Impacts Node H20 – Module 1

In this section SELFINJ and ANXTY were by far the two variables with the smallest strength weights. The weights for these variables were orders of magnitudes smaller than anything else in the diagnostic and were effectively eliminated from the reduced diagnostic. For reference, the weights of these two variables were over 4,000 times smaller than the third-least represented variable.

This suggests it might be possible to eliminate or disregard these variables in a reduced diagnostic.

Every other variable in the original section had a significant weight presence in the reduced diagnostic. The most significant variables were AGG, URBEH, and IMGCR.

7.3.3.1 Correlation Between Variables

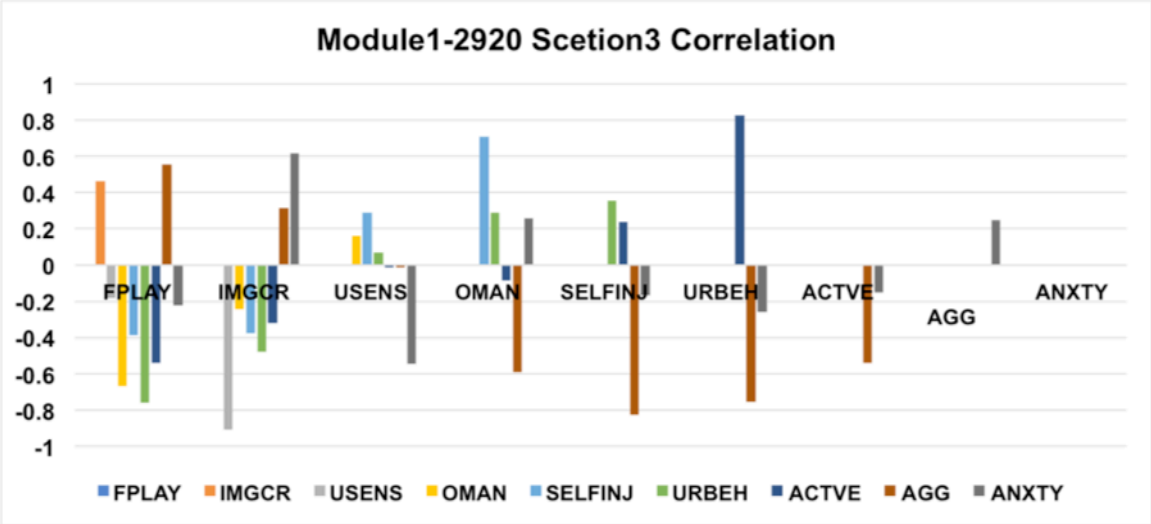

Figure 44. Weights Correlations – Module 1 Section 3

ACTIVE strongly correlates with URBEH, which suggests that increased presence of one variable in a node generally accompanies increased presence of another.

7.4 Module 2 Analysis

The diagram below shows Module 2 Autoencoder with Hidden layer of size 19.

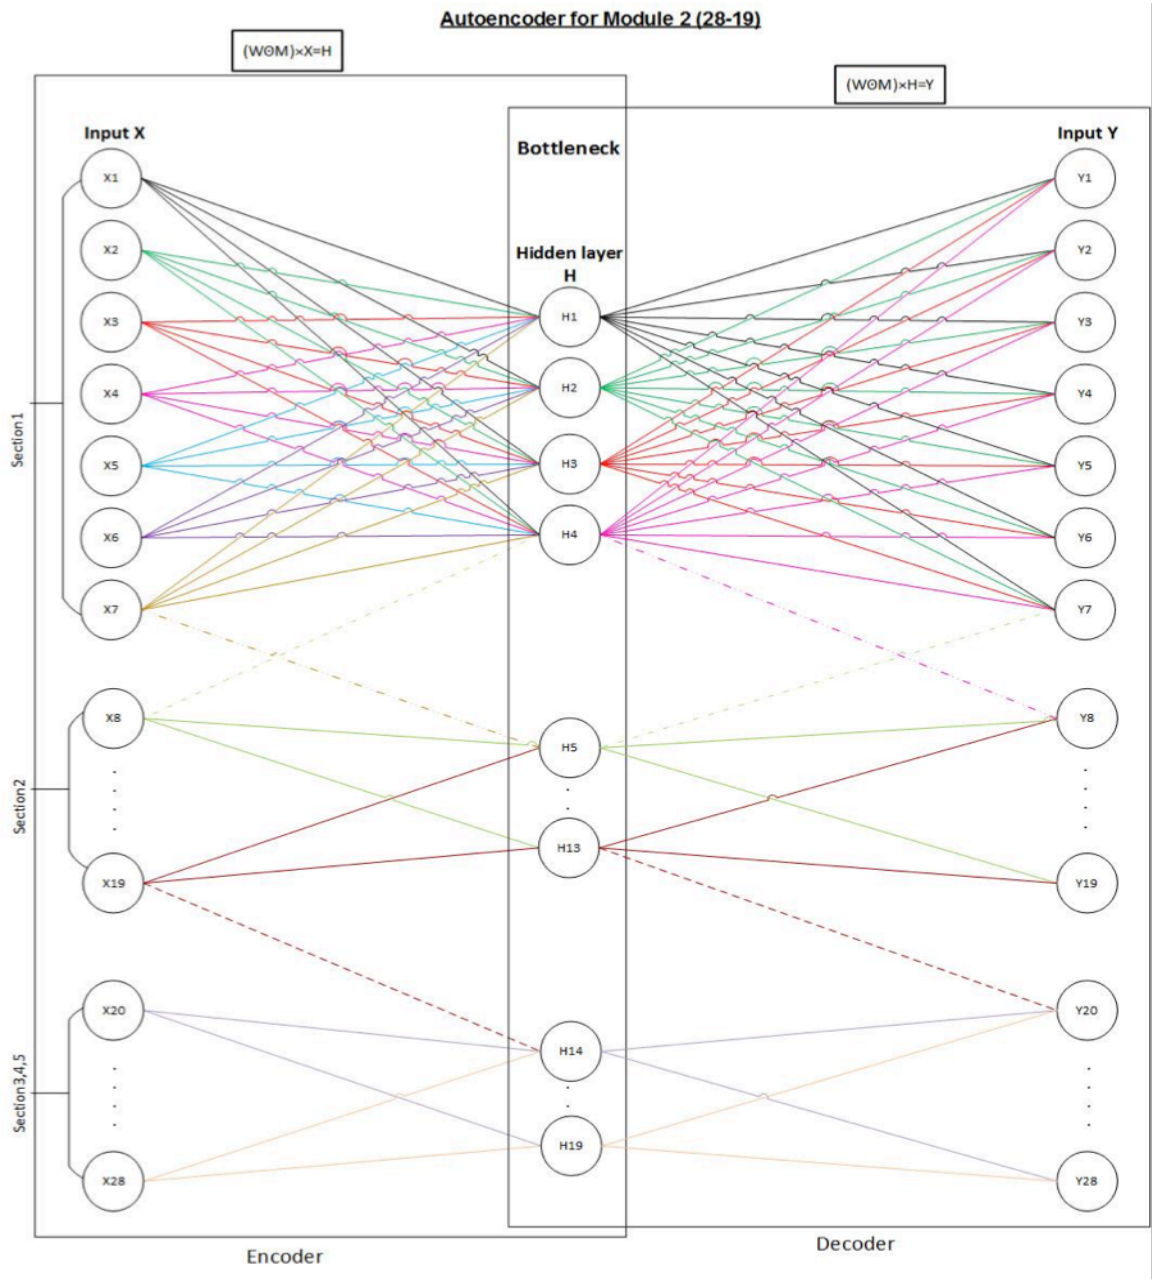

Figure 45. Module 2 Autoencoder with Hidden Layer of Size 19

7.4.1 Module 2 Section 1 Analysis

The first section of Module 2 corresponds to Language and Communication. The 7-variable original section was reduced to a 4-variable section by the autoencoder. The 7 variables in this section are Overall Level of Non-Echoed Spoken Language (OLANG), Speech Abnormalities (SPABN), Immediate Echolalia (IECHO), Stereotyped/Idiosyncratic Use of Words or Phrases (STEREO), Conversation (CONVS), Pointing (POINT), and Descriptive Gestures (DGEST). The diagrams below shows the weights of the reduced diagnostic of this section.

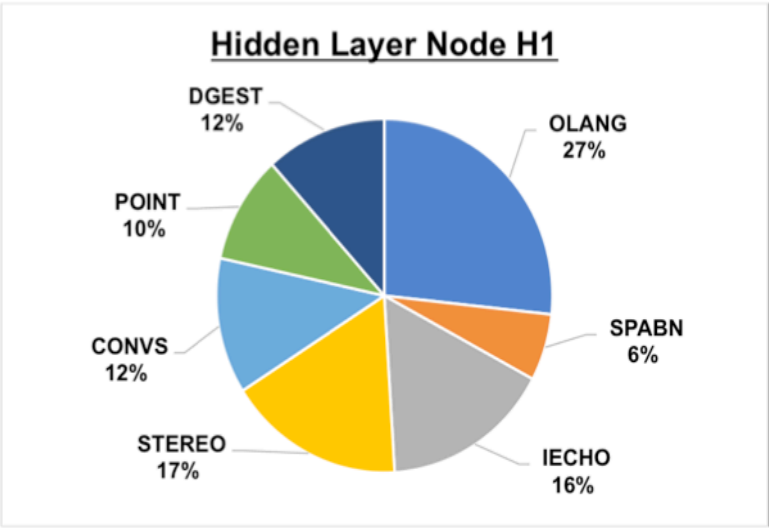

Figure 46. Relative Weights Impacts Node H1 – Module 2

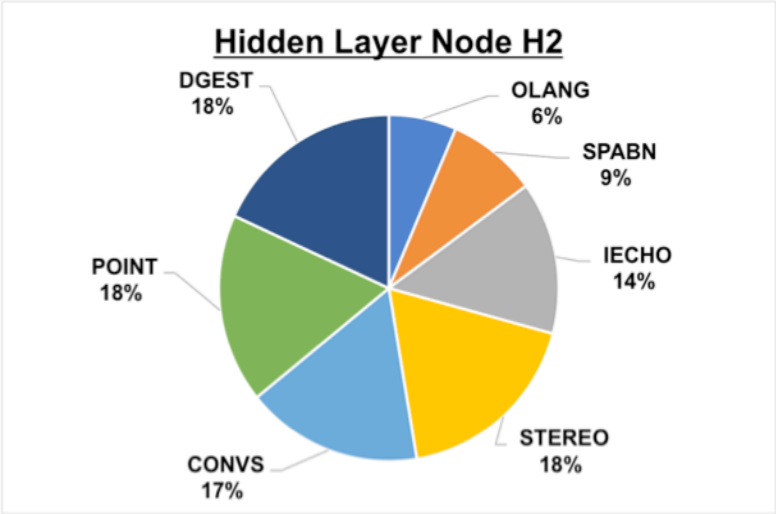

Figure 47. Relative Weights Impacts Node H2 – Module 2

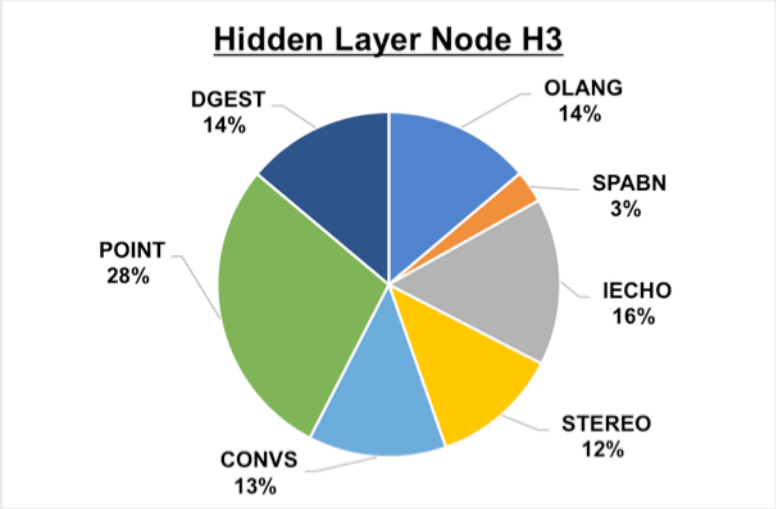

Figure 48. Relative Weights Impacts Node H3 – Module 2

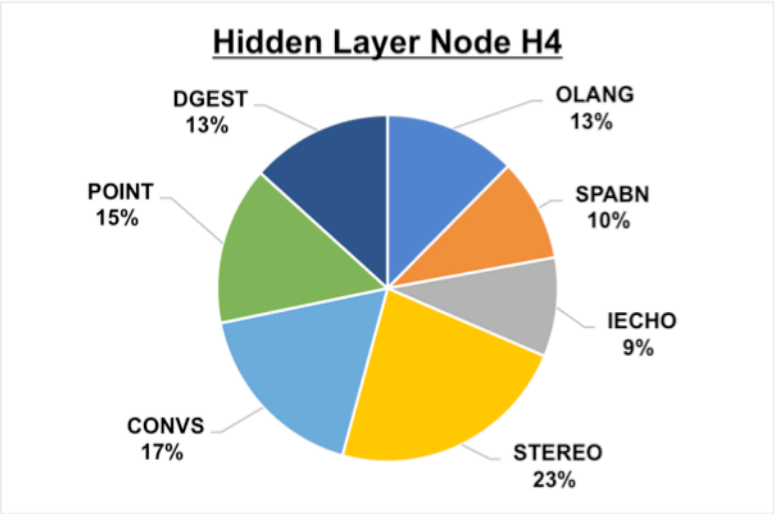

Figure 49. Relative Weights Impacts Node H4 – Module 2

SPABN is the least represented variable by a significant margin. This data suggests that this variable could likely be deprioritized in a reduced diagnostic. None of the variables in this section have negligible weights however. The most represented variables are POINT and STEREO by a significant margin. The other variables, with the exception of SPABN are all closely clustered in the strength of their weights.

7.4.1.1 Correlation Between Variables

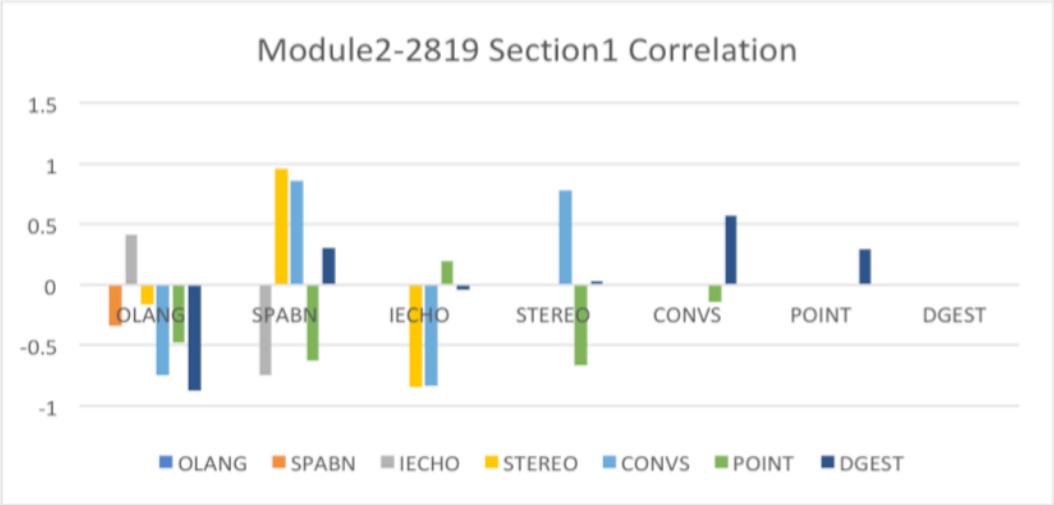

Figure 50. Weights Correlations – Module 2 Section 1

SPABN and STEREO correlate almost perfectly in their weights. SPABN also correlates strongly with CONVS.

7.4.2 Module 2 Section 2 Analysis

Section 2 of Module 2 of the ADOS involves the Subject of Reciprocal Social Interaction. The autoencoder reduced this section from 12 variables to 9 variables. The original 12 variables were Unusual Eye Contact (UEYE), Facial Expressions Directed to Others (FACEO), Shared Enjoyment in Interaction (SHRNJ), Response to Name (RNAME), Showing (SHOW), Spontaneous Initiation of Joint Attention (SIJNT), Response to Joint Attention (RJNT), Amount of Social Overtures (ASOV), Quality of Social Response (QSOV), Amount of Reciprocal Social Communication (ARSOC) and Overall Quality of Rapport

(OQRAP). The diagrams below shows the weights of the reduced diagnostic of this section.

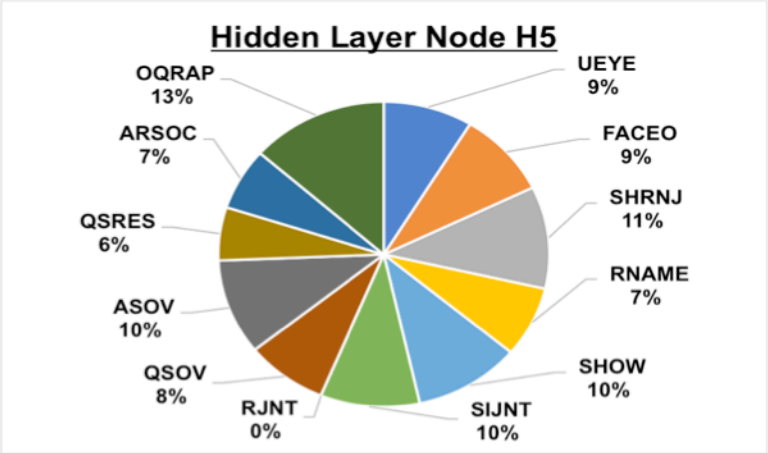

Figure 51. Relative Weights Impacts Node H5 – Module 2

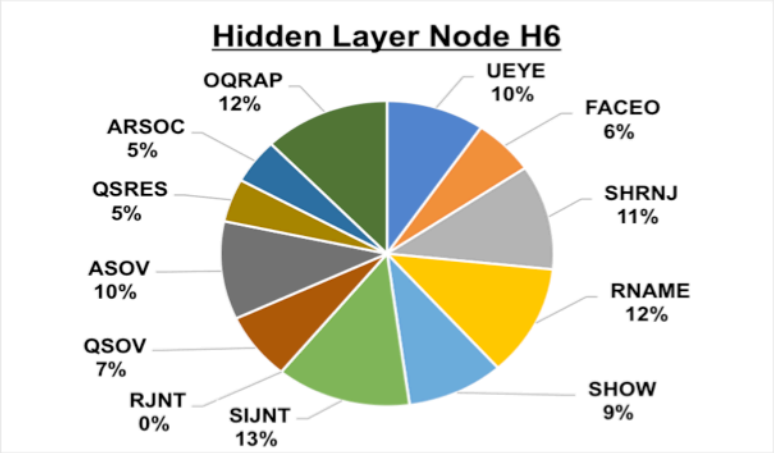

Figure 52. Relative Weights Impacts Node H6 – Module 2

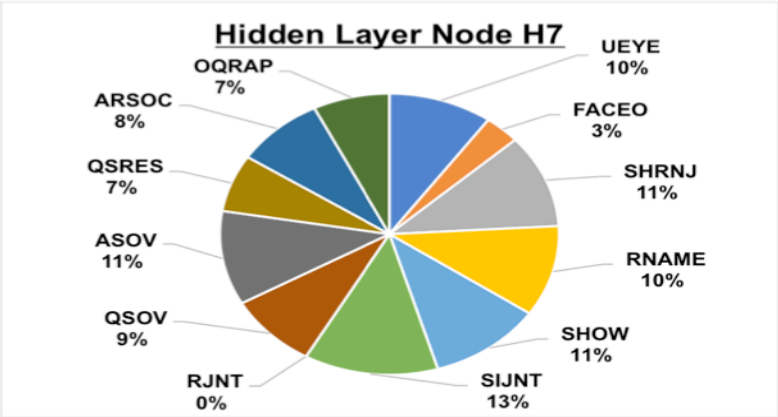

Figure 53. Relative Weights Impacts Node H7 – Module 2

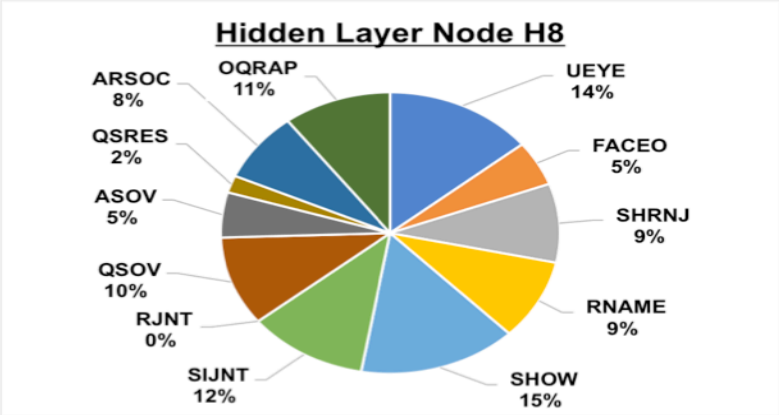

Figure 54. Relative Weights Impacts Node H8 – Module 2

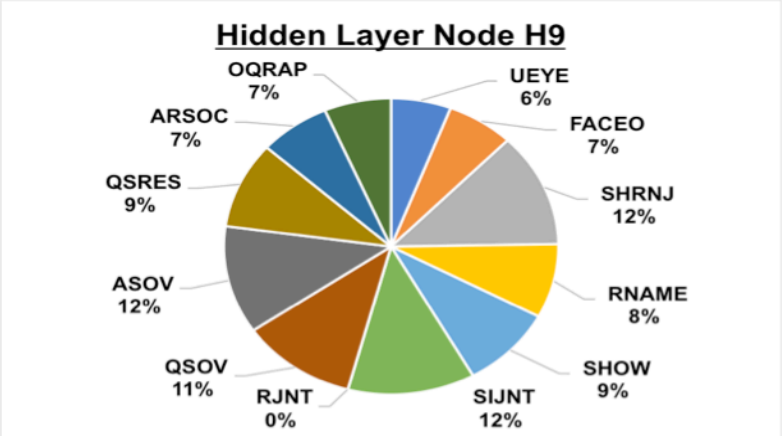

Figure 55. Relative Weights Impacts Node H9 – Module 2

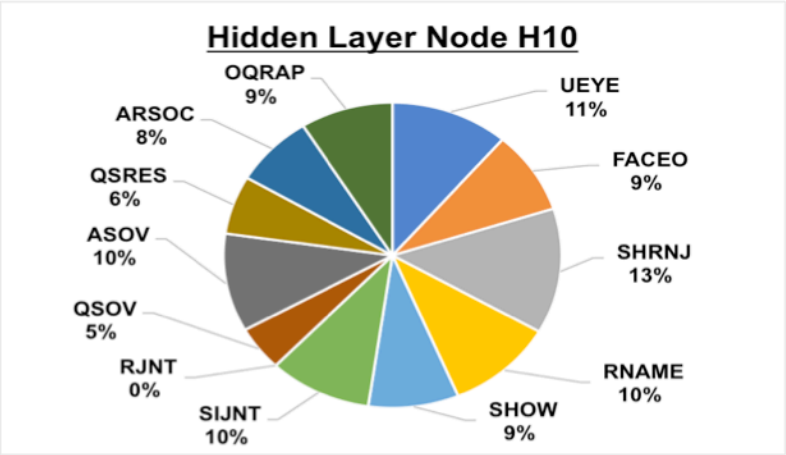

Figure 56. Relative Weights Impacts Node H10 – Module 2

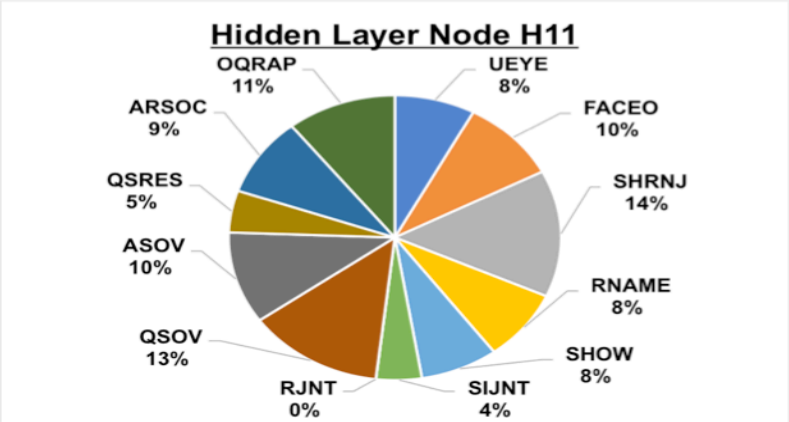

Figure 57. Relative Weights Impacts Node H11 – Module 2

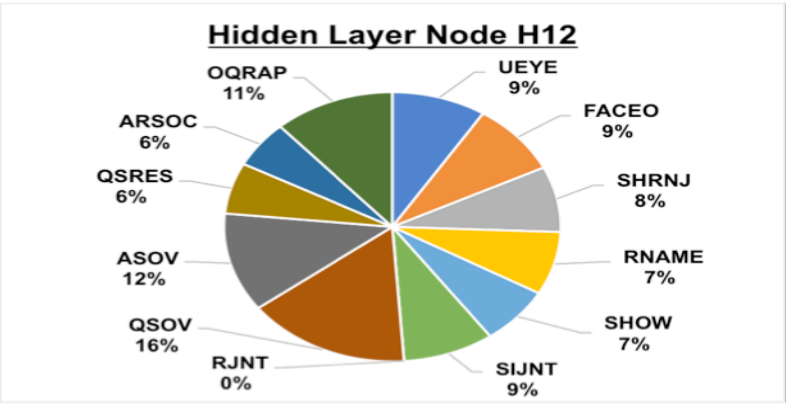

Figure 58. Relative Weights Impacts Node H12 – Module 2

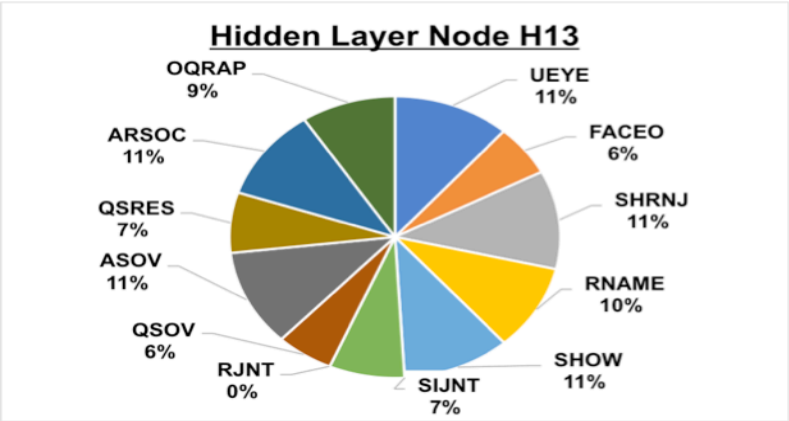

Figure 59. Relative Weights Impacts Node H13 – Module 2

Within the reduced diagnostic nodes, the weights of SIJNT and ARSOC almost perfectly correlate have a correlation of almost 1. Also, ASOV and QSRES correlate with each other with a near perfect correlation.

RJIT was by far the least represented variable in the reduced diagnostic for this section. Its weights were over 100 times smaller than the second least represented variable. Every other variable in this section had significant weights. SHRNJ had the most significant presence. ASOV, OQRAP, SIJNT, SHOW and UEYE followed, and were also closely clustered.

7.4.2.1 Correlation Between Variables

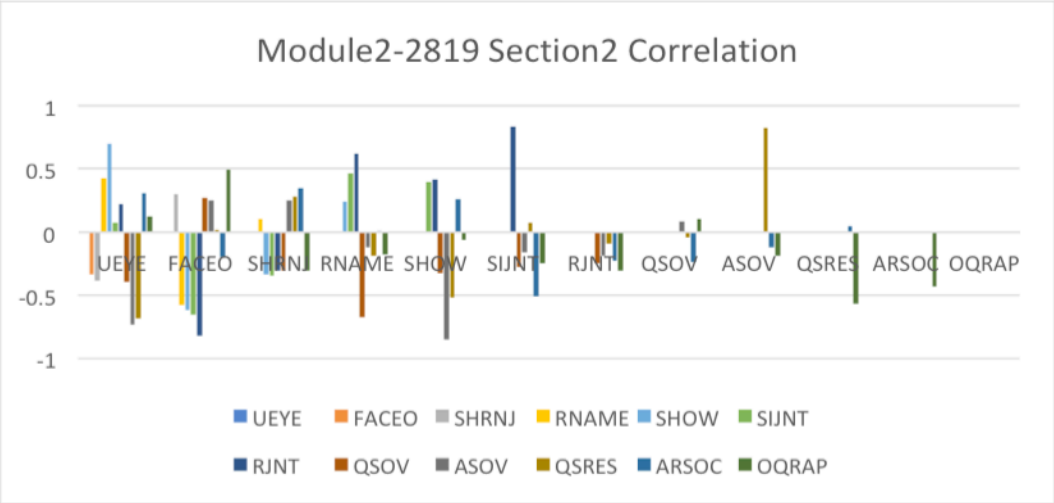

Figure 60. Weights Correlations – Module 2 Section 2

UEYE and SHOW demonstrate a strong positive correlation in weight strength. SIJNT and RJNT also strongly correlate in weight presence, which makes sense given their similar subject nature. Last, OQRAP and FACEO have a strong correlational relationship.

7.4.3 Module 2 Section 3 Analysis

The third section of the reduced Module 2 autoencoder involved reducing 9 original ADOS variables into 6 new ones. The 9 original variables spanned the subjects of Play, Stereotyped Behaviors/Restricted Interests, and Other Abnormal Behaviors. The original variables were Functional Play with Objects (FPLAY), Imagination/Creativity (IMGCR), Unusual Sensory Interest in Play Material/Person (USENS), Hand and Finger and Other Complex Mannerisms (OMAN), Self-Injurious Behavior (SELFINJ), Unusually Repetitive

Interests or Stereotyped Behaviors (URBEH), Overactivity (ACTIVE), Tantrums, Aggression, Negative or Disruptive Behavior (AGG), and Anxiety (ANXTY). The diagrams below shows the weights of the reduced diagnostic of this section.

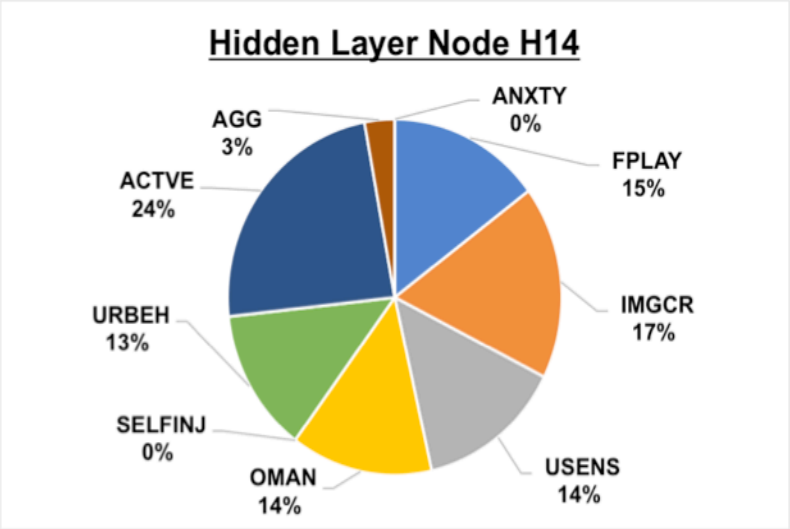

Figure 61. Relative Weights Impacts Node H14 – Module 2

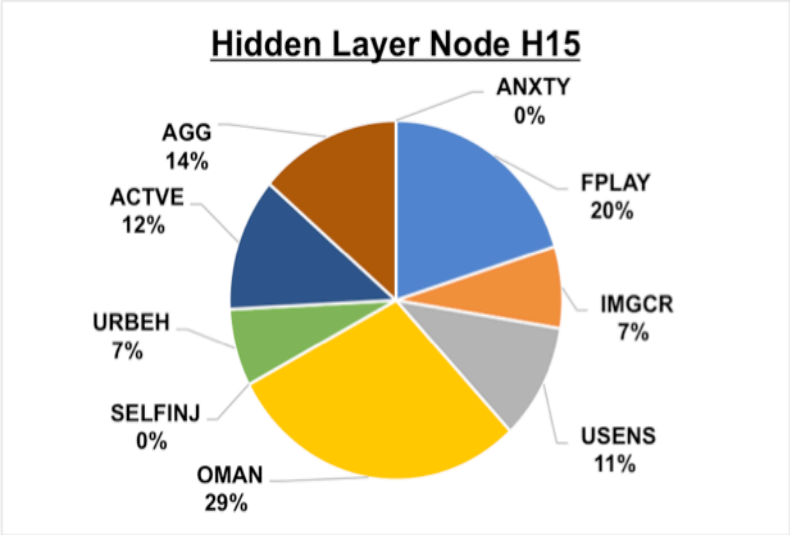

Figure 62. Relative Weights Impacts Node H15 – Module 2

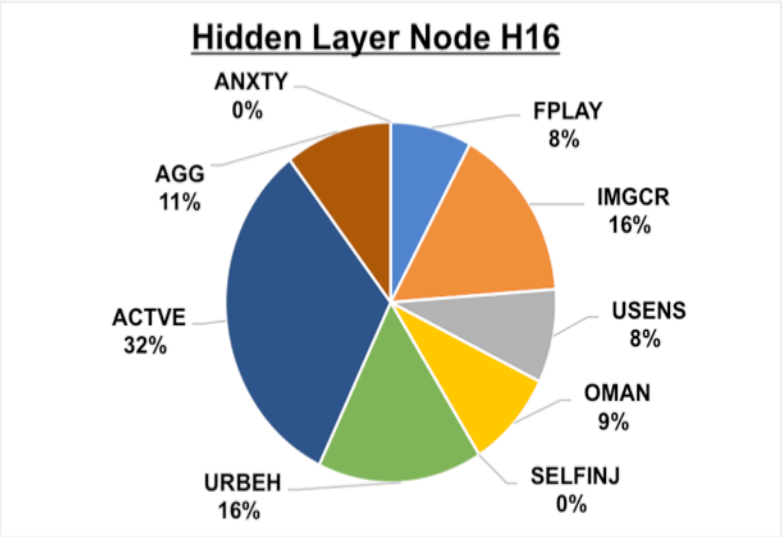

Figure 63. Relative Weights Impacts Node H16 – Module 2

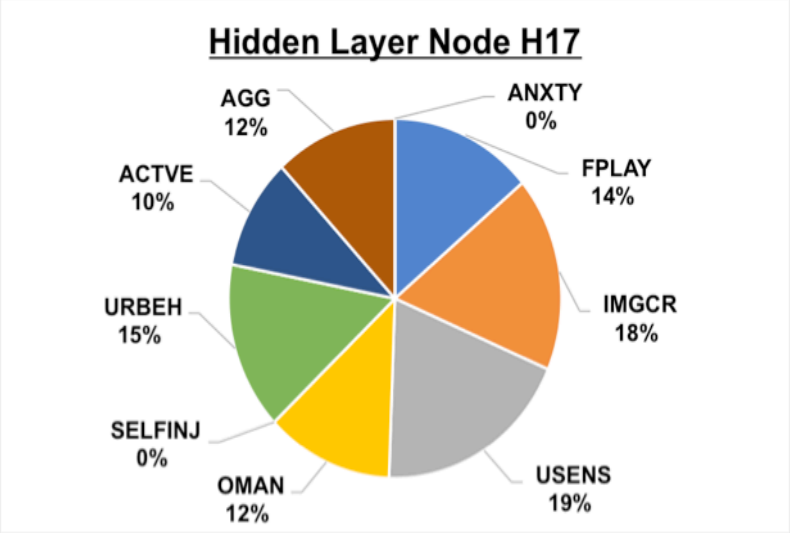

Figure 64. Relative Weights Impacts Node H17 – Module 2

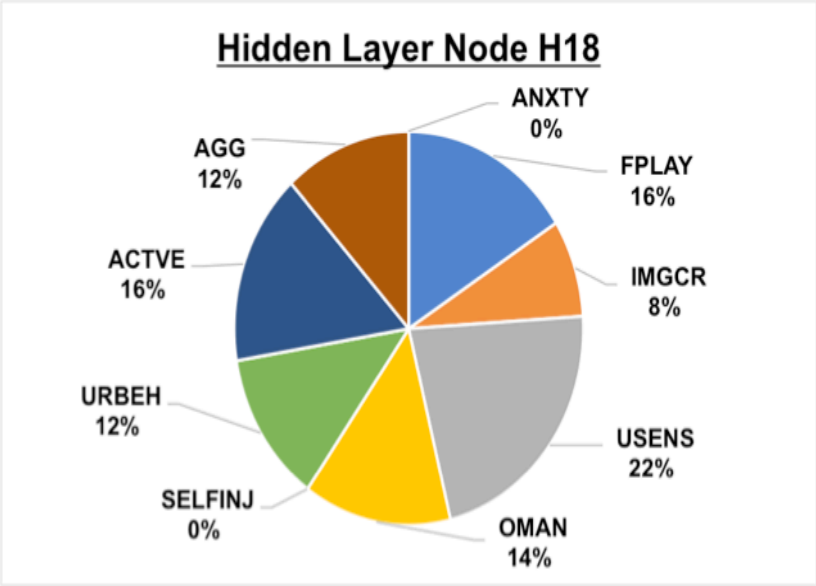

Figure 65. Relative Weights Impacts Node H18 – Module 2

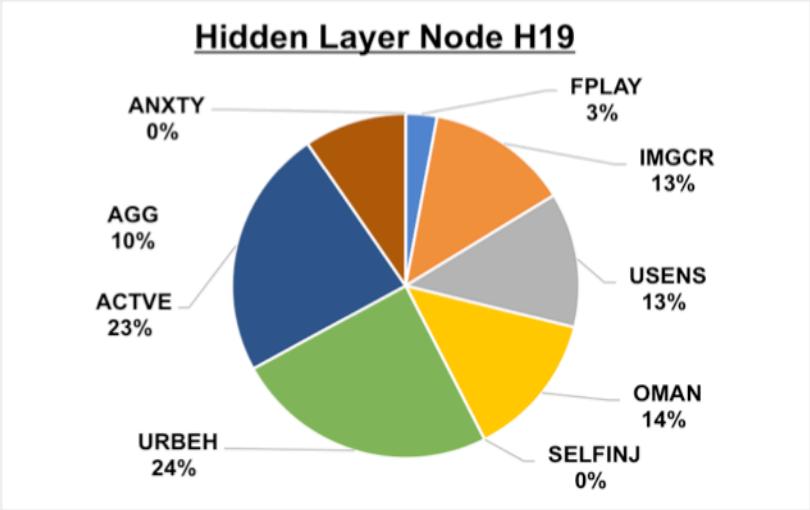

Figure 66. Relative Weights Impacts Node H19 – Module 2

Once again, SELFINJ and ANXTY were by far the least represented variables, as they had completely negligible weights. They were over 1,000 times less influential than any other variables, and were effectively dropped from the diagnostic by the autoencoder. ACTIVE and “OMAN” were the two variables with

greatest representation, and all variables besides the two that were mentioned were represented adequately.

7.4.3.1 Correlation Between Variables

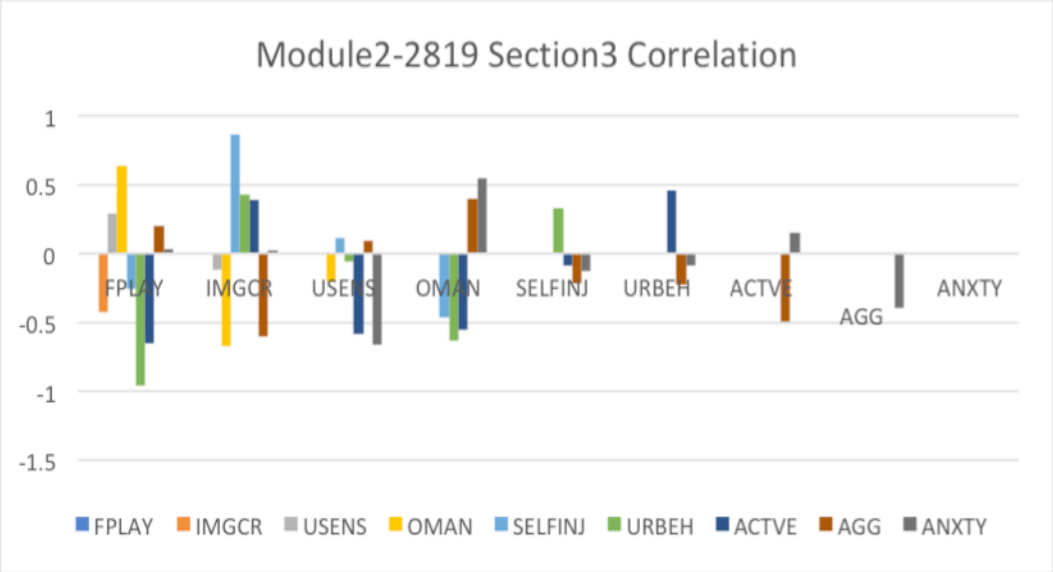

Figure 67. Weights Correlations – Module 2 Section 3

IMGCE and SELFINJ have a strong correlational relationship, although this is probably meaningless given the latter variable's negligible presence in nodes.

7.5 Module 3 Analysis

The diagram below shows Module 3 Autoencoder with Hidden layer of size 19.

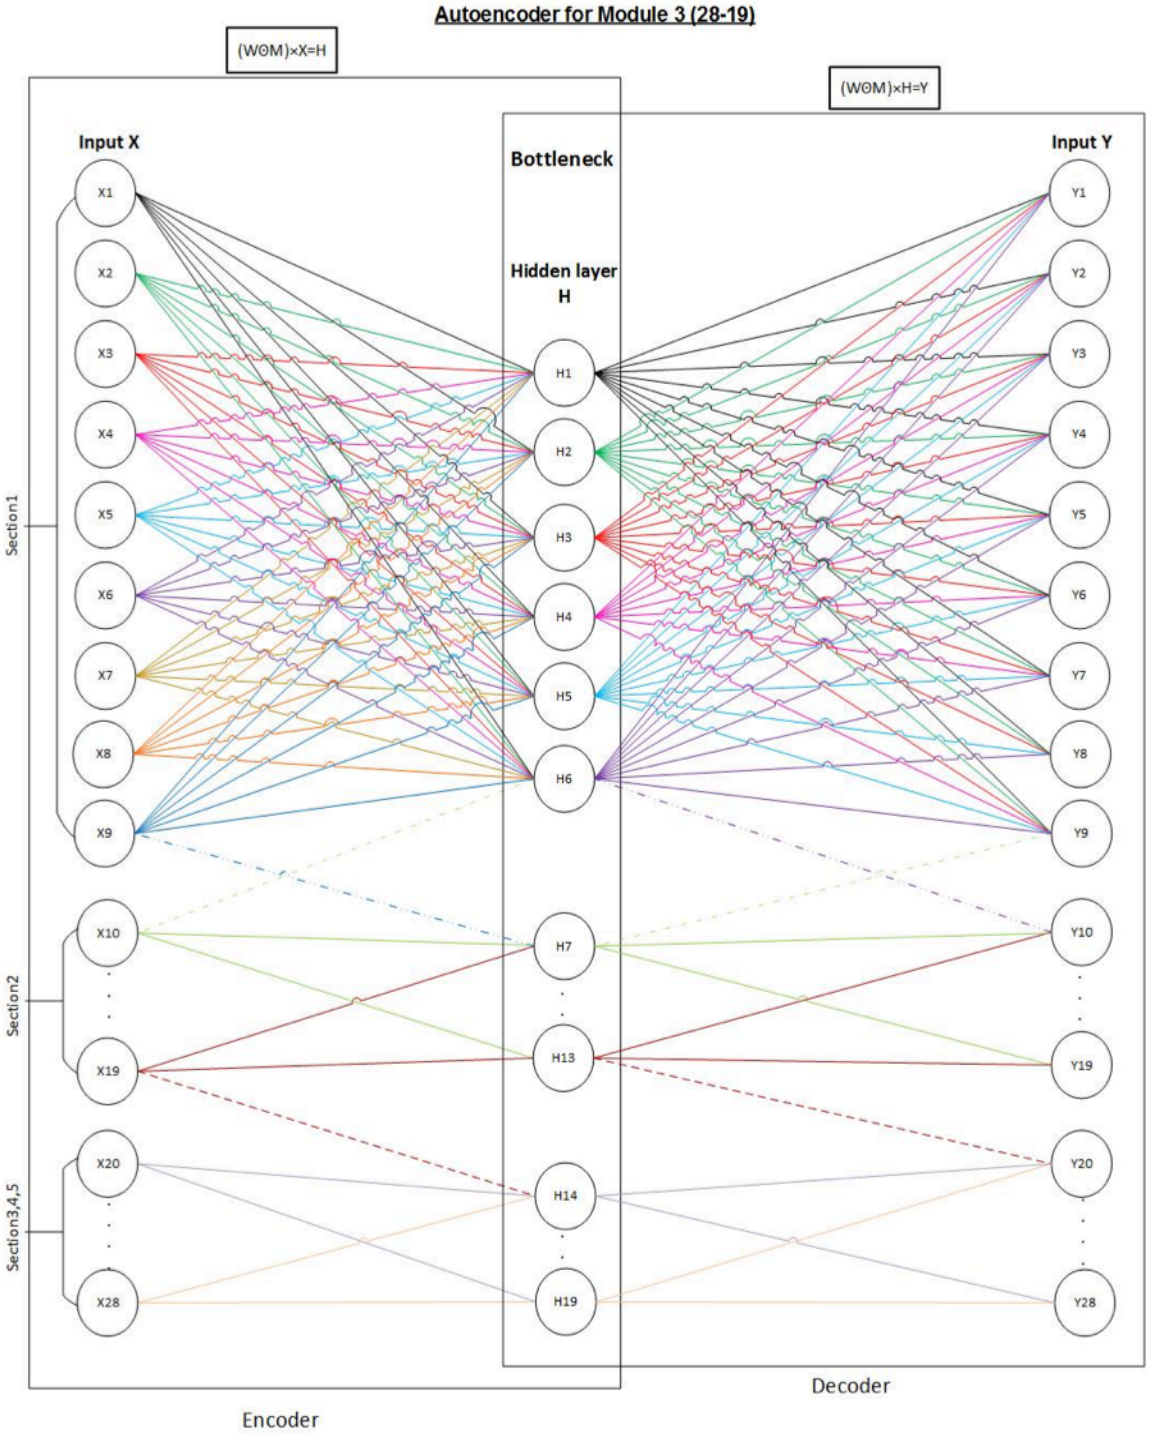

Figure 68. Module 3 Autoencoder with Hidden Layer of Size 19

7.5.1 Module 3 Section 1 Analysis

The first section of Module 3 corresponds to Language and Communication. The 9-variable original section was reduced to a 6-variable section by the autoencoder. The 9 variables in this section are Overall Level of Non-Echoed Spoken Language (OLANG), Speech Abnormalities (SPABN), Immediate Echolalia (IECHO), Stereotyped/Idiosyncratic Use of Words or Phrases (STEREO), Offers Information (OINFO), Asks for Information (AINFO), Reporting of Events (REPRT), Conversation (CONVS), and Descriptive Gestures (DGEST). The diagrams below shows the weights of the reduced diagnostic of this section.

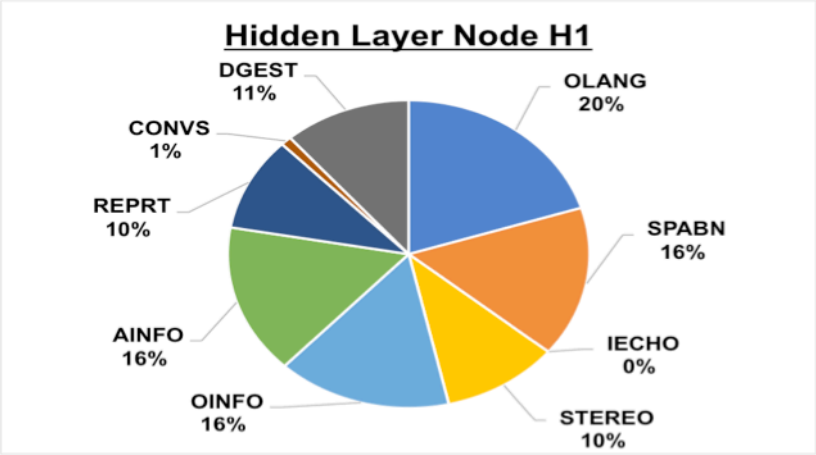

Figure 69. Relative Weights Impacts Node H1 – Module 3

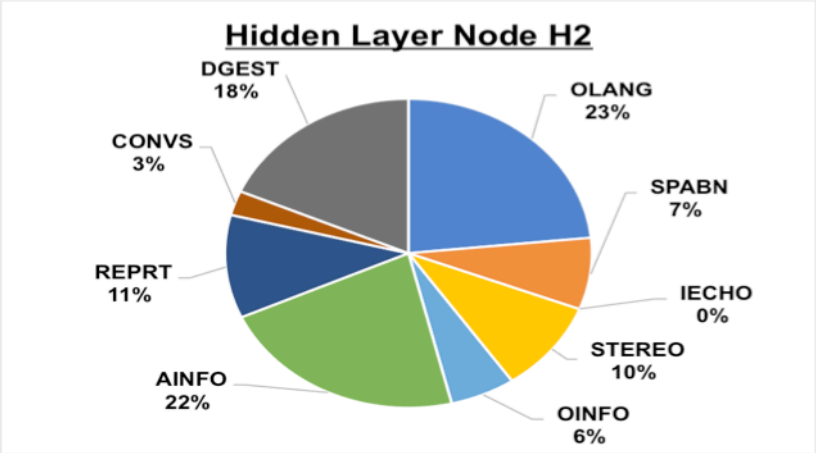

Figure 70. Relative Weights Impacts Node H2 – Module 3

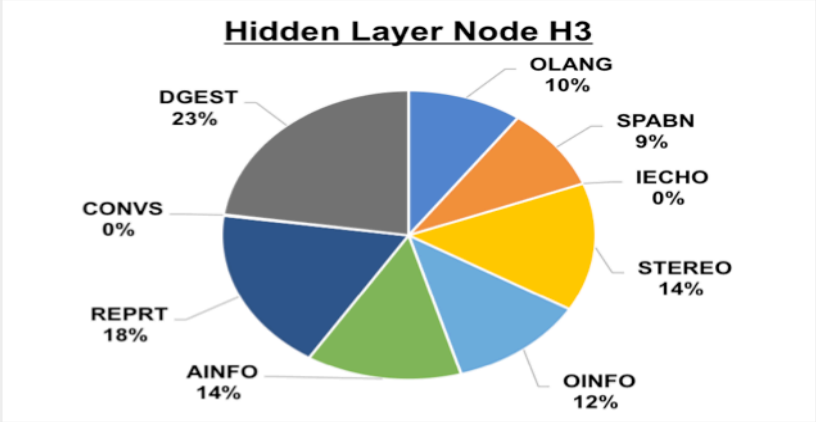

Figure 71. Relative Weights Impacts Node H3 – Module 3

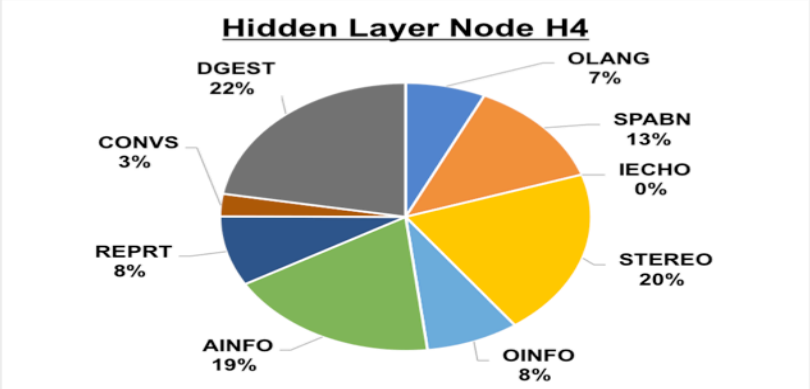

Figure 72. Relative Weights Impacts Node H4 – Module 3

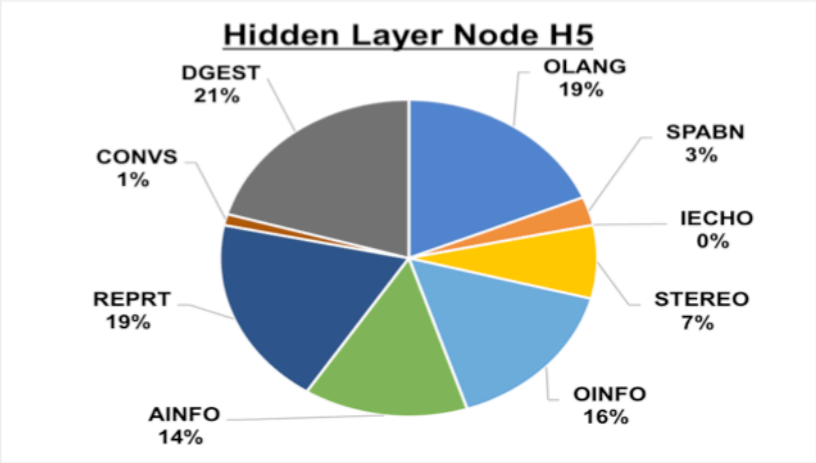

Figure 73. Relative Weights Impacts Node H5 – Module 3

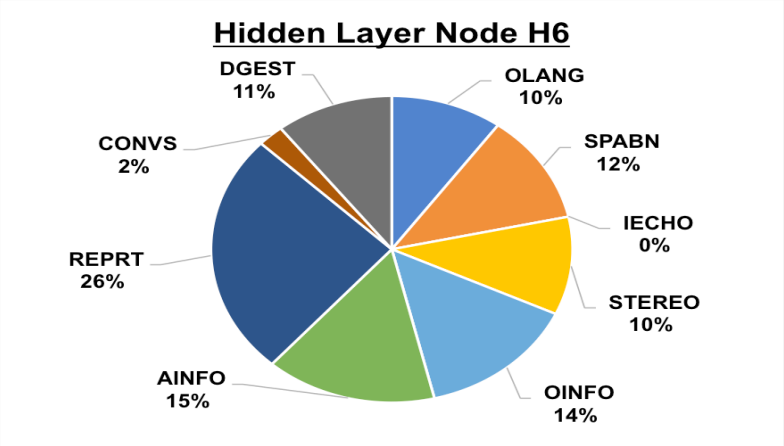

Figure 74. Relative Weights Impacts Node H6 – Module 3

IECHO was almost completely dropped from the diagnostic, as its weights were several orders of magnitude smaller than any others in the section. CONVS was the second least represented variable. While its weights were significantly higher than IECHO, it lagged significantly behind the other variables.

All other weights were fairly strong, with DGEST as the highest, followed by AINFO, REPRT and OLANG. These variables had weights significantly than the other variables.

7.5.1.1 Correlation Between Variables

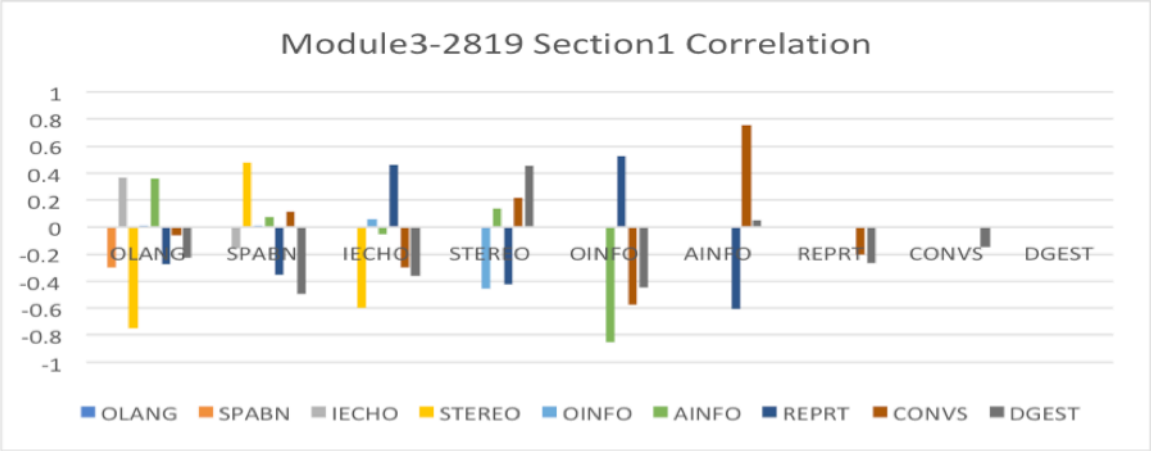

Figure 75. Weights Correlations – Module 3 Section 1

AINFO and CONVS have a strong positive correlational relationship.

7.5.2 Module 3 Section 2 Analysis

Section 2 of Module 3 involves Reciprocal Social Interaction. The original diagnostic included 10 variables, and the reduced diagnostic contains 7 variables. The variables are Unusual Eye Contact (UEYE), Facial Expressions Directed to Examiner (FACEO), Language Production and Linked Nonverbal Communication (LLNVC), Shared Enjoyment in Interaction (SHRNJ), Comments on Others' Emotions/Empathy (EMPTH), Insight into Typical Social Situations and Relationships (INSIG), Quality of Social Overtures (QSOV), Quality of Social

Response (QSRES), Amount of Reciprocal Social Communication (ARSOC), and Overall Quality of Rapport (OQRAP). The diagrams below shows the weights of the reduced diagnostic of this section.

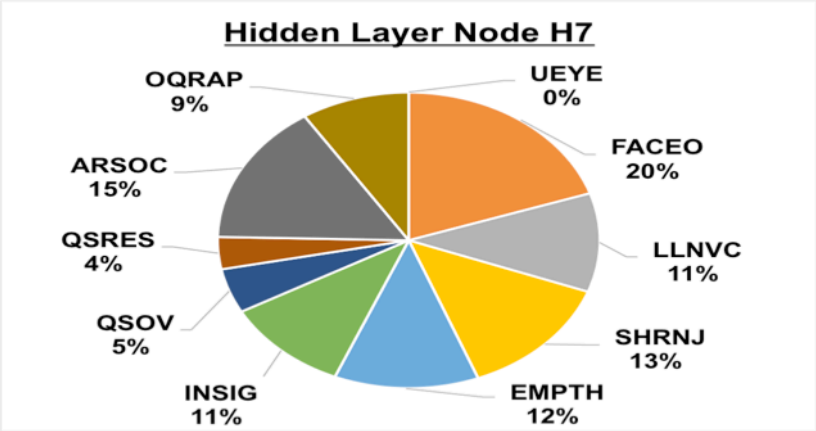

Figure 76. Relative Weights Impacts Node H7 – Module 3

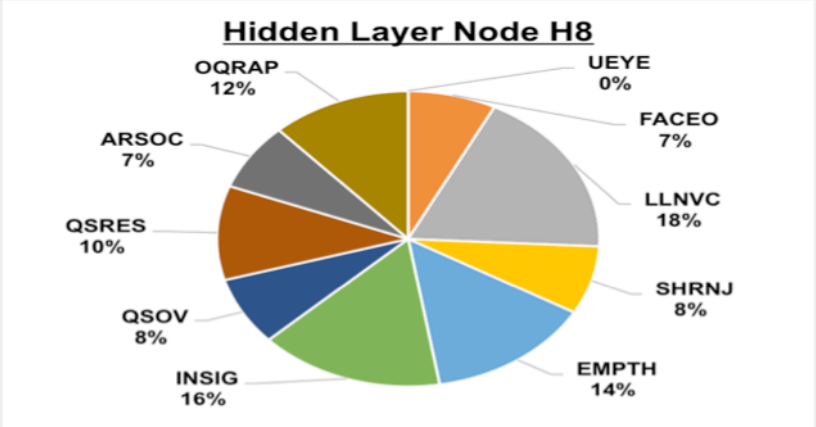

Figure 77. Relative Weights Impacts Node H8 – Module 3

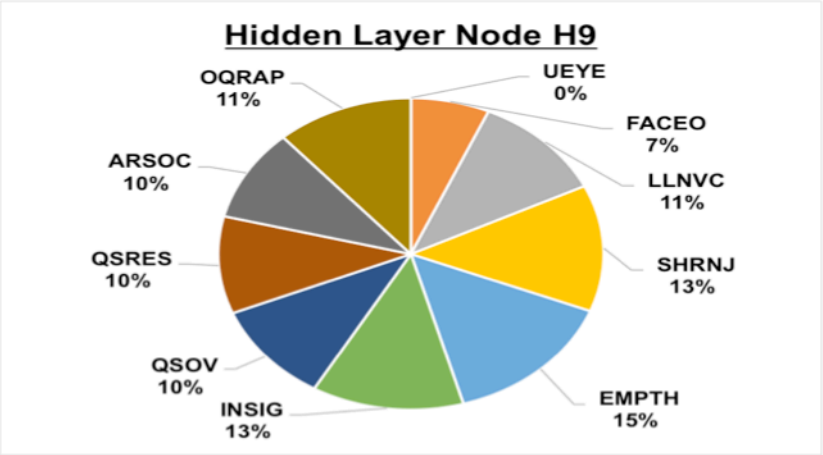

Figure 78. Relative Weights Impacts Node H9 – Module 3

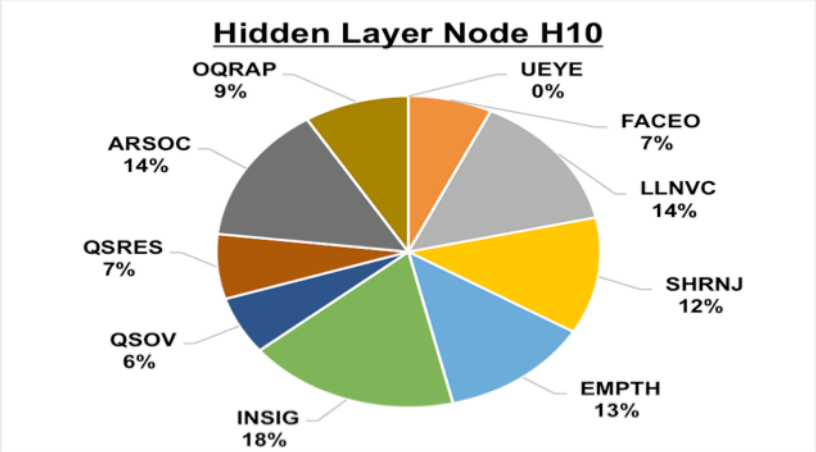

Figure 79. Relative Weights Impacts Node H10 – Module 3

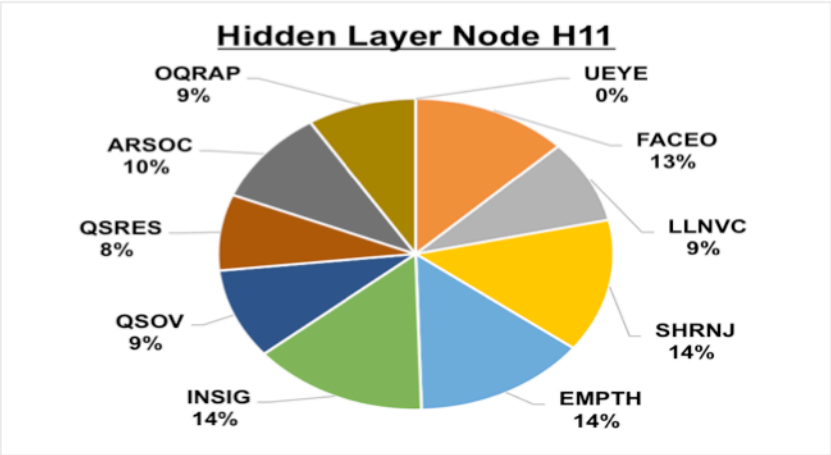

Figure 80. Relative Weights Impacts Node H11 – Module 3

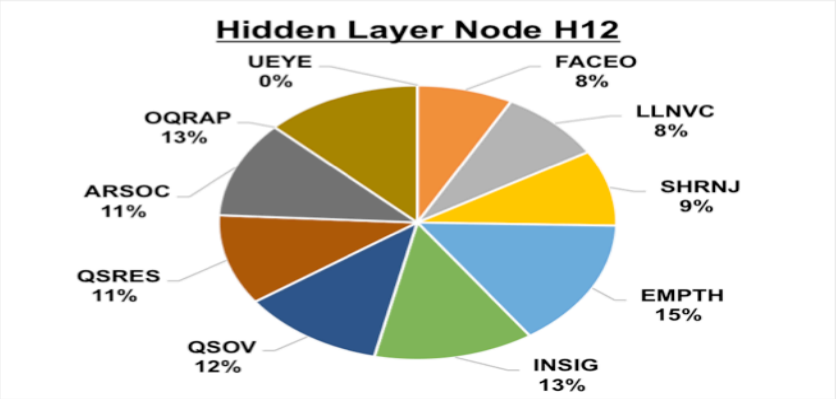

Figure 81. Relative Weights Impacts Node H12 – Module 3

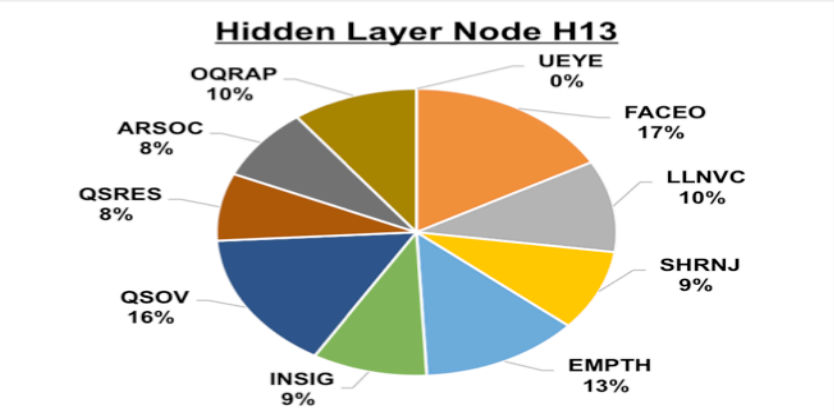

Figure 82. Relative Weights Impacts Node H13 – Module 3

UEYE was the least represented variable by a large margin and was effectively dropped from the reduced diagnostic in this instance. All other variables had significant weights attached. EMPTHY and INSIG were the most impactful variables by a significant margin. The majority of the other variables were clustered closely together in weight strength, with QSRES and QSOV slightly lagging behind the others.

75.2.1 Correlation Between Variables

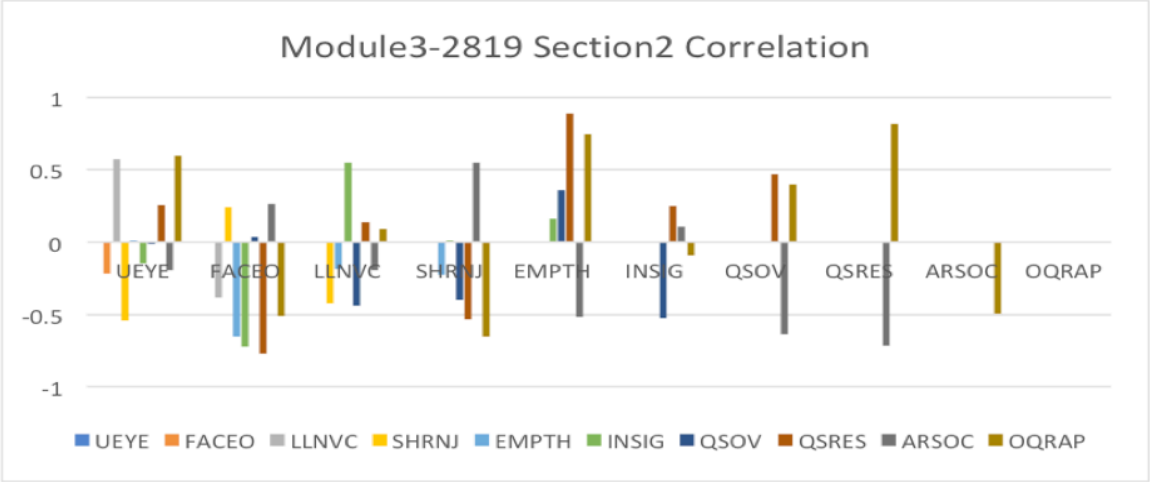

Figure 83. Weights Correlations – Module 3 Section 2

EMPTH and QSRES have a strong correlational relationship in weight presence. OQRAP also correlates strongly with both EMPTH and QSRES. These correlations indicate shared occurrences between these three variables in some capacity.

7.5.3 Module 3 Section 3 Analysis

The third section of the reduced diagnostic combines sections in the original that cover Imagination, Stereotyped Behaviors/Restricted Interests, and Other Abnormal Behaviors. There were 9 variables originally in these sections, and these were reduced to 6 variables by the autoencoders. The variables in these sections are Imagination/Creativity (IMGCR), Unusual Sensory Interest In Play Material/Person (USENS), Hand and Finger and Other Complex Mannerisms (OMAN), Self-Injurious Behavior (SELFINJ), Excessive Interest in or References to Unusual or Highly Specific Topics or Objects or Repetitive Behaviors (TOPIC), Compulsions or Rituals (RITL), Overactivity/Agitation (ACTIVE), Tantrums/Aggression (AGG), and Anxiety (ANXTY). The diagrams below shows the weights of the reduced diagnostic of this section.

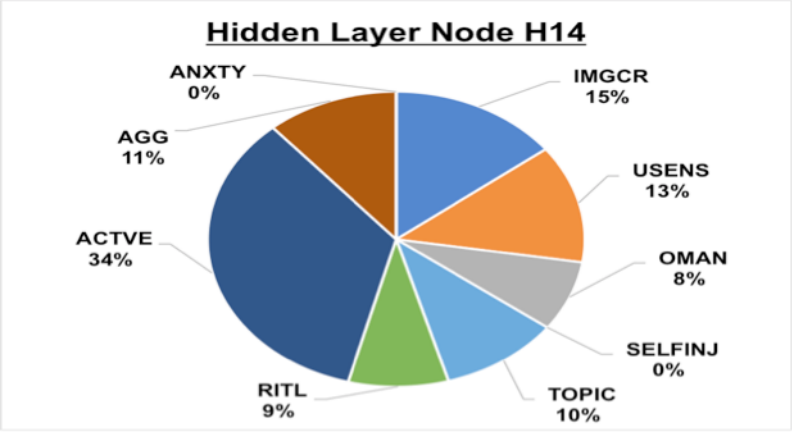

Figure 84. Relative Weights Impacts Node H14 – Module 3

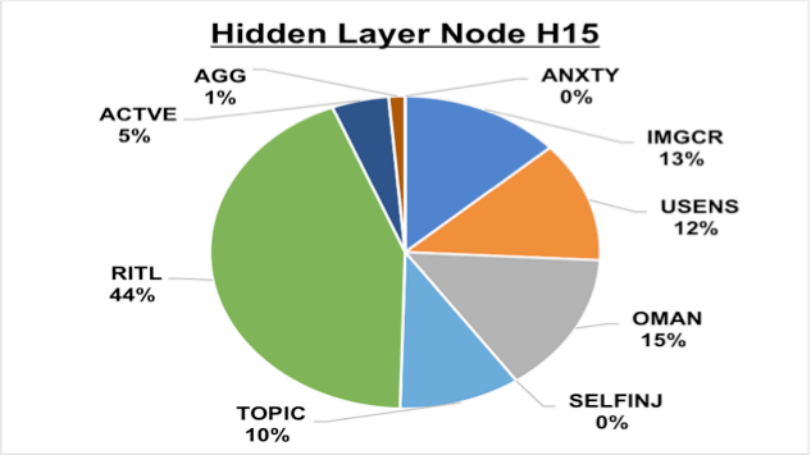

Figure 85. Relative Weights Impacts Node H15 – Module 3

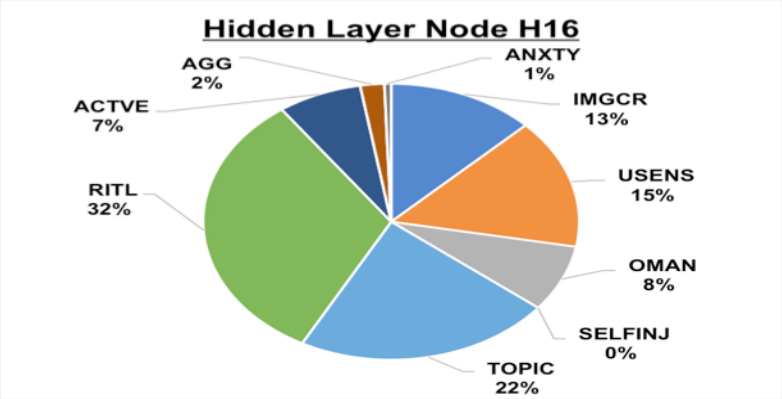

Figure 86. Relative Weights Impacts Node H16 – Module 3

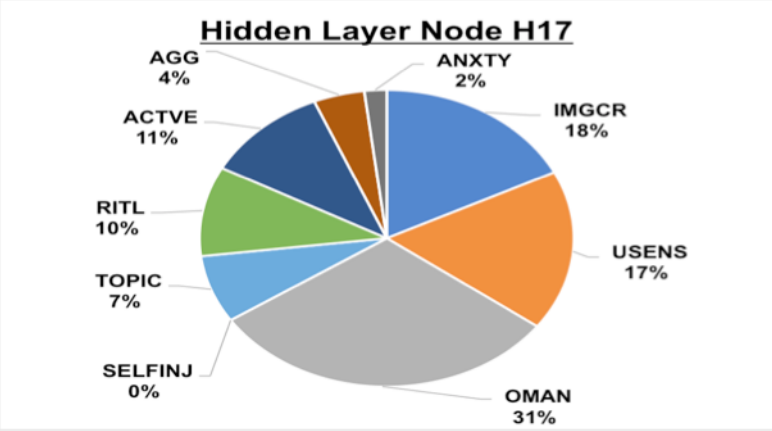

Figure 87. Relative Weights Impacts Node H17 – Module 3

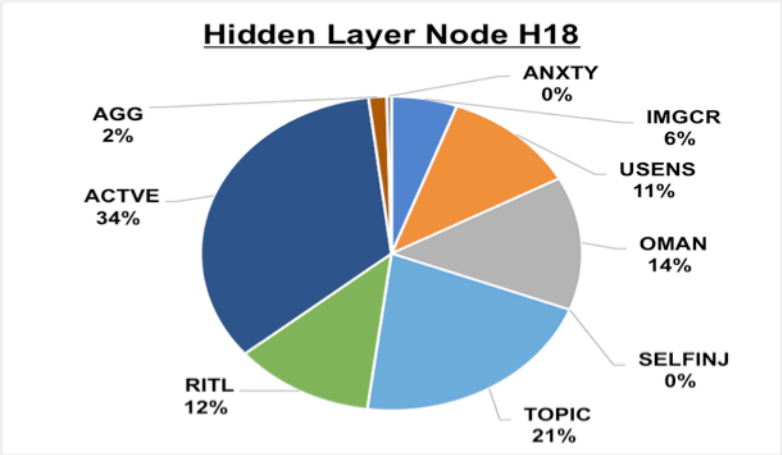

Figure 88. Relative Weights Impacts Node H18 – Module 3

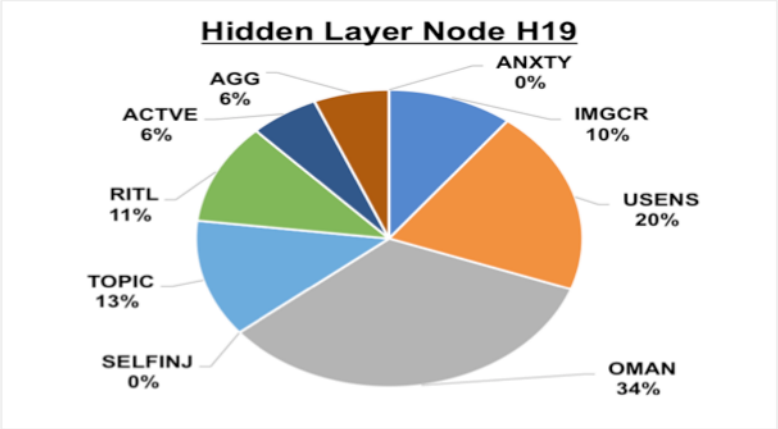

Figure 89. Relative Weights Impacts Node H19 – Module 3

As in earlier cases, SELFINJ had by far the weakest weights, orders of magnitude below anything else. ANXTY also had very weak weights that were significantly below everything else. Nonetheless, there was a sizeable gap between ANXTY and SELFINJ". All other weights were fairly strong, with TOPIC or RITL, OMAN, and ACTIVE demonstrating the strongest connections by a solid margin. The other variables were clustered close together with the exception of

AGG, which lagged behind other variables but ahead of the two least important ones.

7.5.3.1 Correlation Between Variables

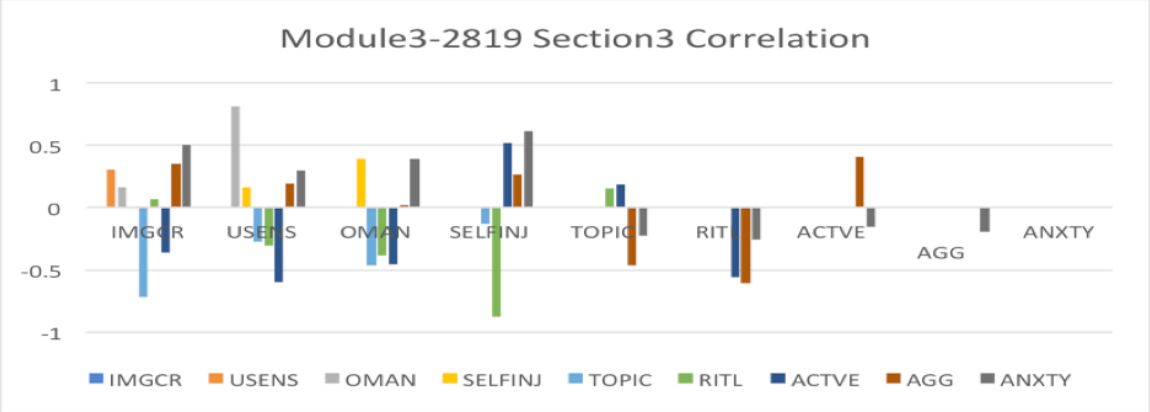

Figure 90. Weights Correlations – Module 3 Section 3

USENS and OMAN show a strong positive correlational relationship.

7.6 Module 4 Analysis

The diagram below shows Module 4 Autoencoder with Hidden layer of size 19.

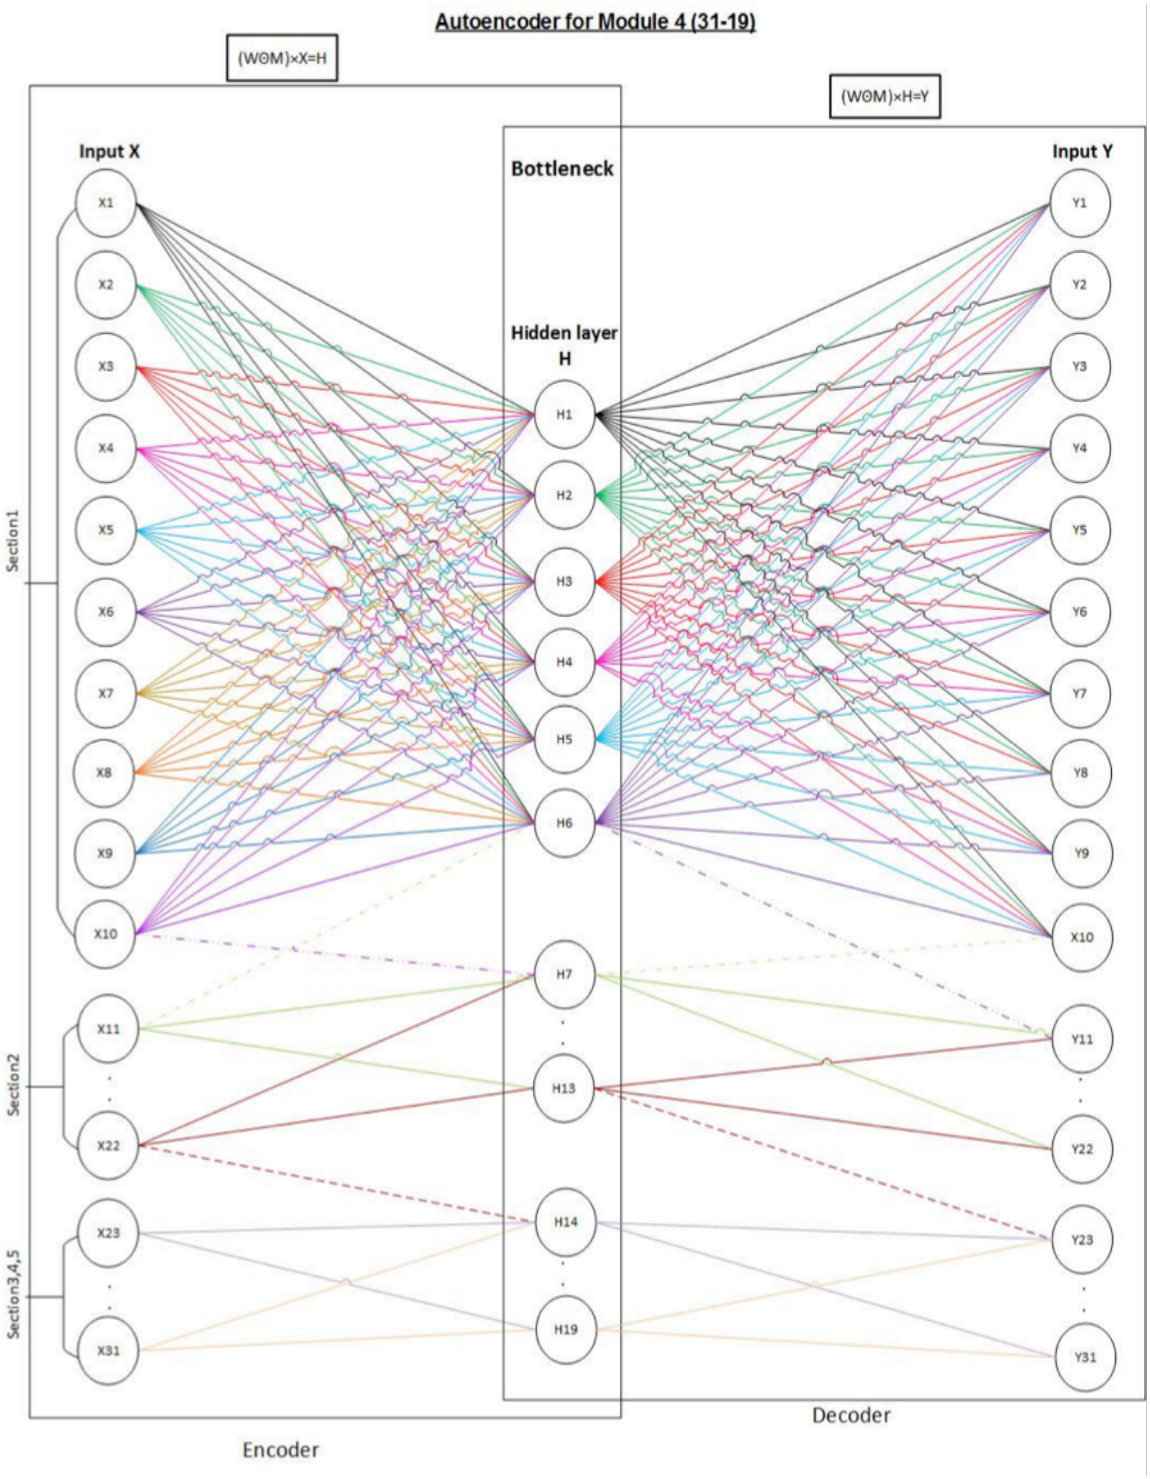

Figure 91. Module 4 Autoencoder with Hidden Layer of Size 19

7.6.1 Module 4 Section 1 Analysis

The first section of Module 4 corresponds to Language and Communication. The 10-variable original section was reduced to a 6-variable section by the autoencoder. The 10 variables in this section are Overall Level of Non-Echoed Spoken Language (OLANG), Speech Abnormalities (SPABN), Immediate Echolalia (IECHO), Stereotyped/Idiosyncratic Use of Words or Phrases (STEREO), Offers Information (OINFO), Asks for Information (AINFO), Reporting of Events (REPRT), Conversation (CONVS), Descriptive Gestures (DGEST), Emphatic or Emotional Gestures (EGEST). The diagrams below shows the weights of the reduced diagnostic of this section.

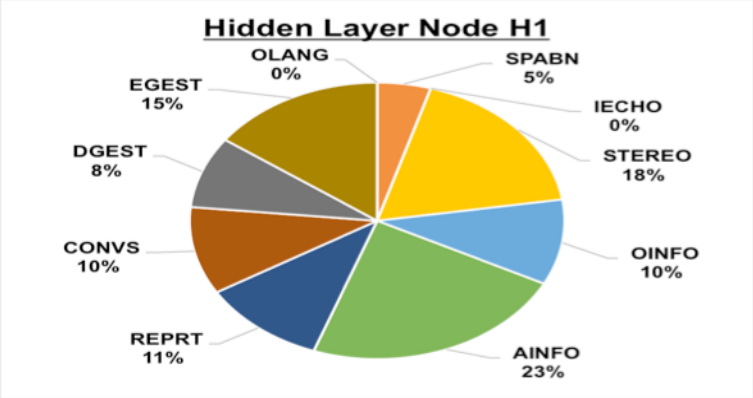

Figure 92. Relative Weights Impacts Node H1 – Module 4

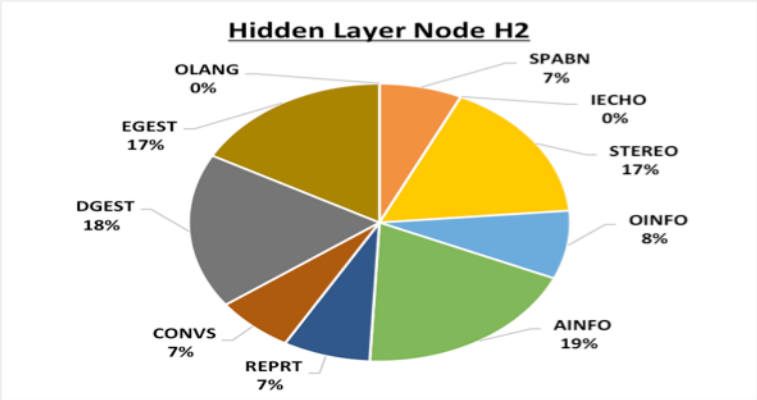

Figure 93. Relative Weights Impacts Node H2 – Module 4

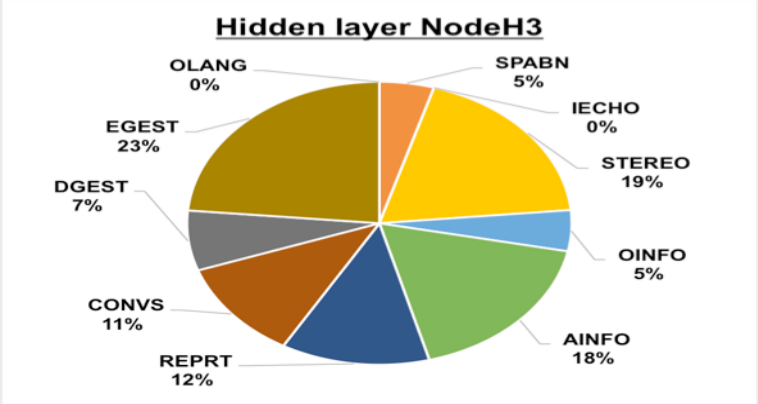

Figure 94. Relative Weights Impacts Node H3 – Module 4

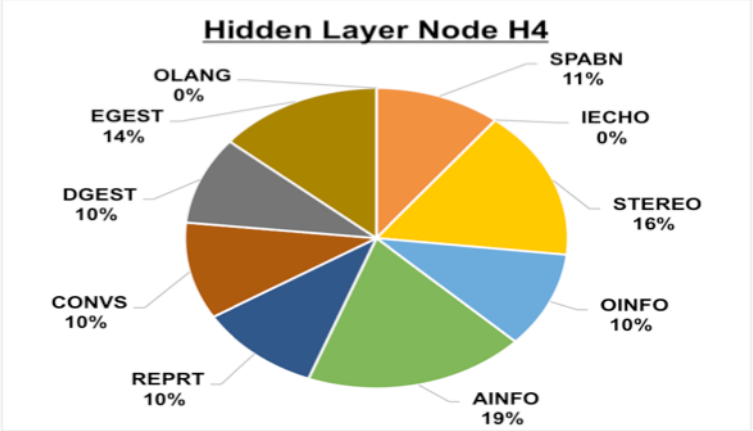

Figure 95. Relative Weights Impacts Node H4 – Module 4

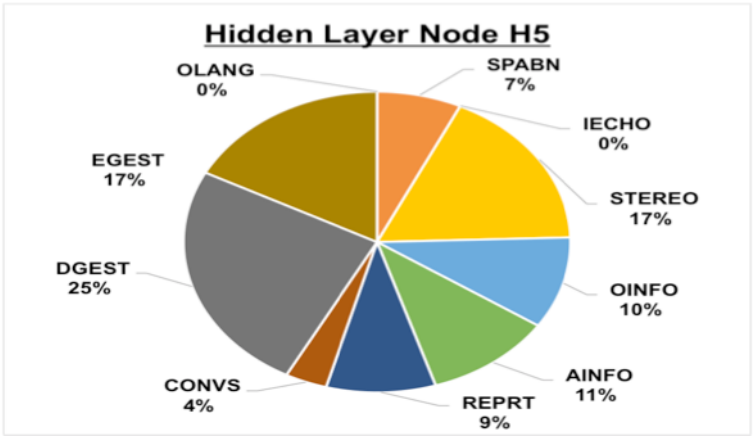

Figure 96. Relative Weights Impacts Node H5 – Module 4

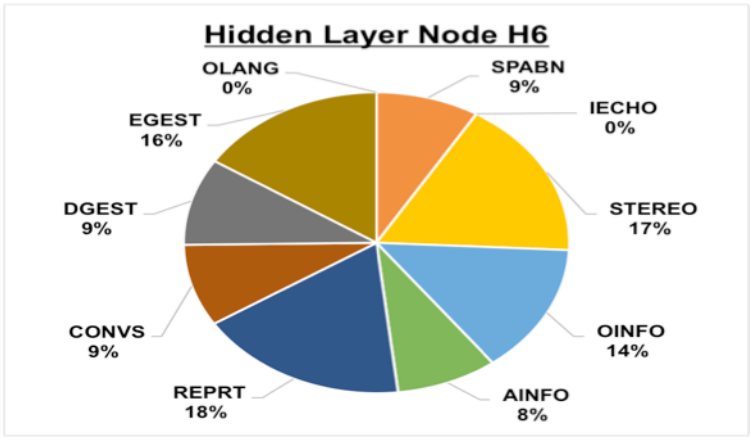

Figure 97. Relative Weights Impacts Node H6 – Module 4

OLANG and IECHO were the two least represented variables and had weights with absolute values several orders of magnitude smaller than the other variables. All other variables were represented with significant weights, with STEREO, EGEST, and AINFO leading the pack. Those three variables had weights higher than the others by a notable amount.

7.6.1.1 Correlation Between Variables

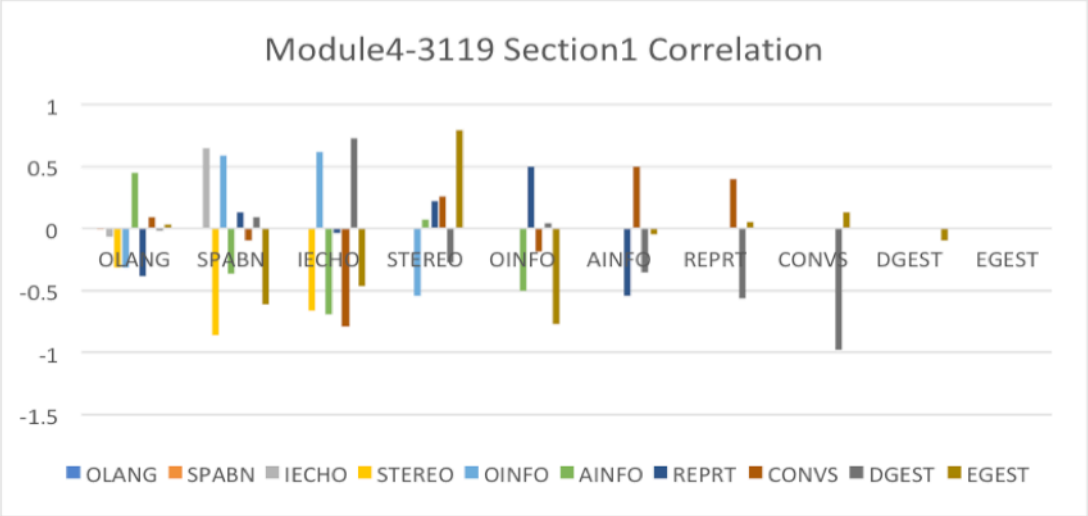

Figure 98. Weights Correlations – Module 4 Section 1

STEREO AND EGEST correlated positively to a strong degree.

7.6.2 Module 4 Section 2 Analysis

Section 3 of Module 4 involves Reciprocal Social Interaction. The original diagnostic included 12 variables, and the reduced diagnostic contains 7 variables. The variables are Unusual Eye Contact (UEYE), Facial Expressions Directed to Examiner (FACEO), Language Production and Linked Nonverbal Communication (LLNVC), Shared Enjoyment in Interaction (SEI), Communication of Own Affect (CAFF), Comments on Others' Emotions/Empathy (EMPTH), Insight into Typical Social Situations and Relationships (INSIG), Responsibility (RESP), Quality of Social Overtures (QSOV), Quality of Social Response (QSRES), Amount of Reciprocal Social Communication (ARSOC), and Overall

Quality of Rapport (OQRAP). The diagrams below shows the weights of the reduced diagnostic of this section.

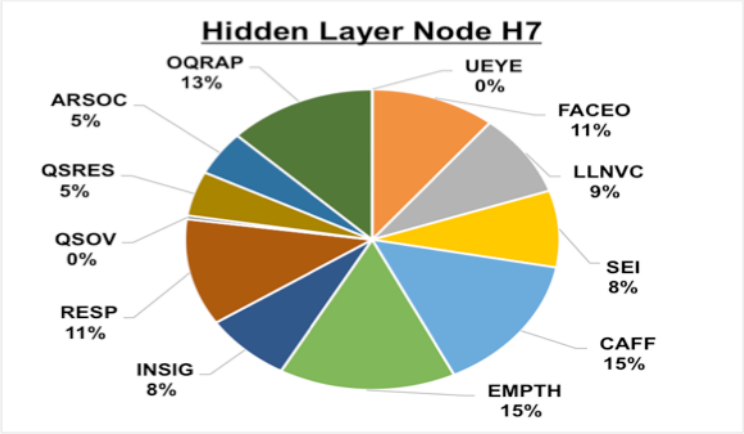

Figure 99. Relative Weights Impacts Node H7 – Module 4

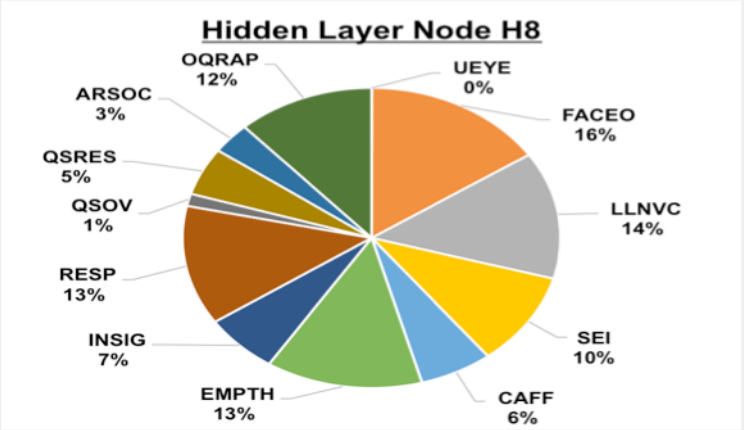

Figure 100. Relative Weights Impacts Node H8 – Module 4

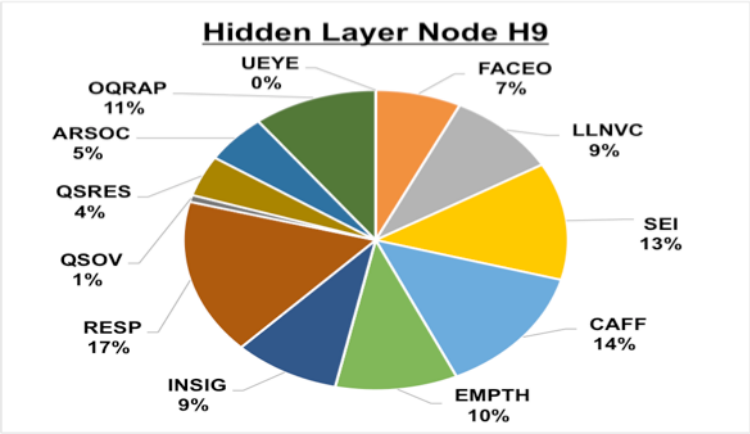

Figure 101. Relative Weights Impacts Node H9 – Module 4

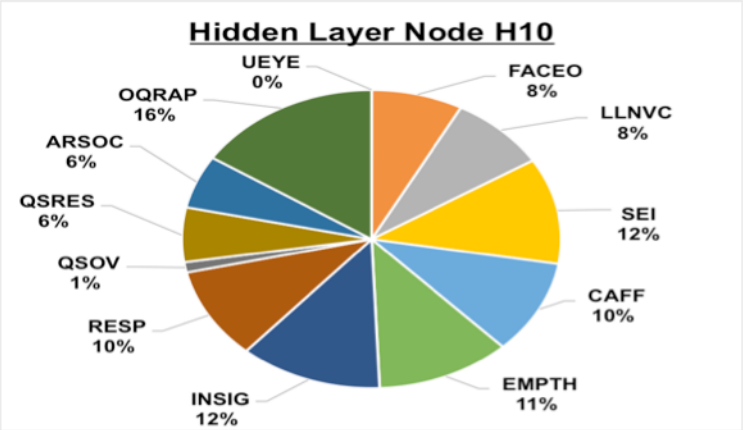

Figure 102. Relative Weights Impacts Node H10 – Module 4

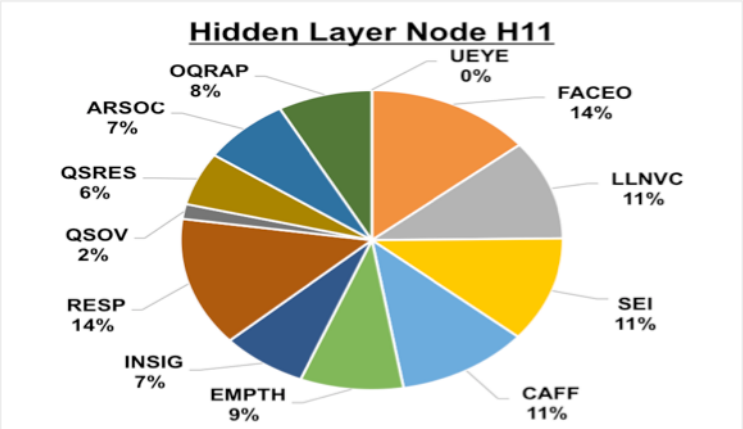

Figure 103. Relative Weights Impacts Node H11 – Module 4

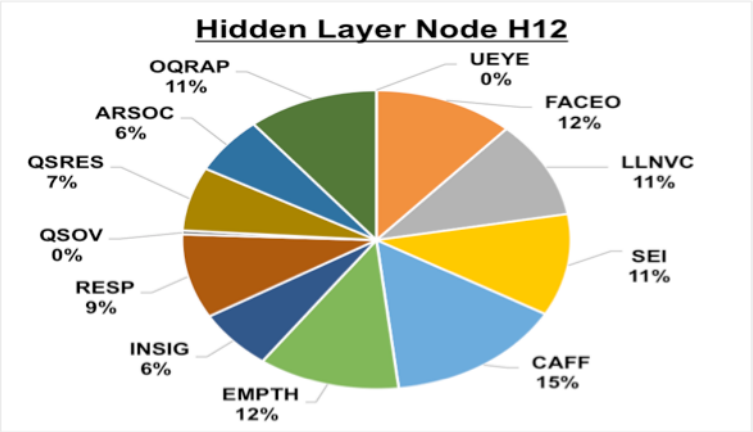

Figure 104. Relative Weights Impacts Node H12 – Module 4

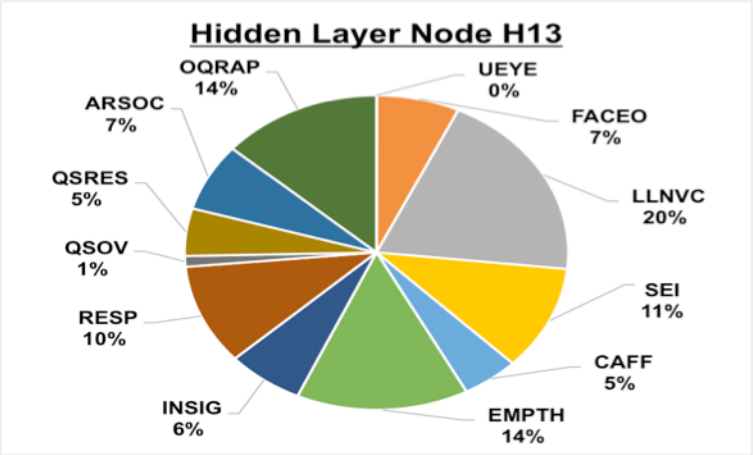

Figure 105. Relative Weights Impacts Node H13 – Module 4

UEYE had the lowest absolute value weights by a large amount. It was effectively removed from the reduced diagnostic. QSOV was clearly the second least important input variable to the reduced diagnostic. QSRES and ARSOC were the next two variables in order of ascending absolute value weights, and had almost identical weights, at a significantly higher level than QSOV. INSIG was the next variable in ascending order. All other variables were closely

clustered together, with Others EMPTH featuring the highest absolute value weights.

7.6.2.1 Correlation Between Variables

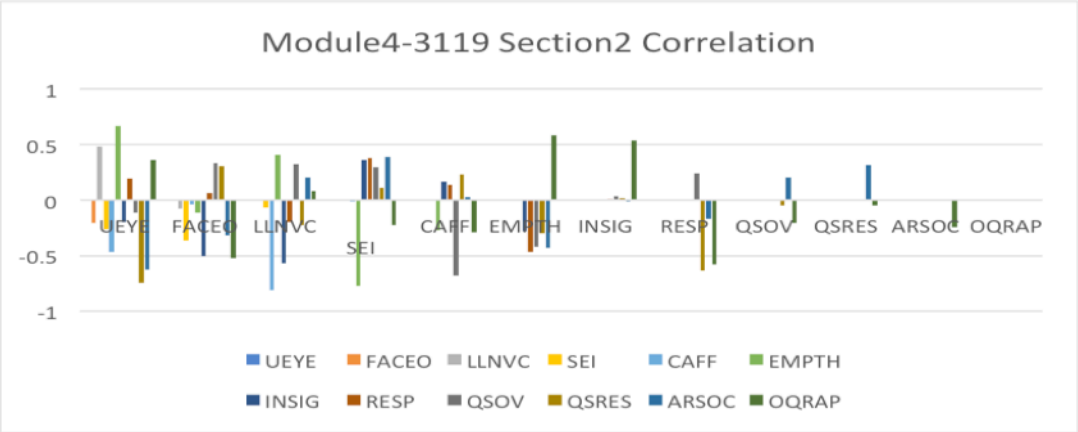

Figure 106. Weights Correlations – Module 4 Section 2

All correlation in this section are weak.

7.6.3 Module 4 Section 3 Analysis

The third section of the reduced diagnostic combines sections in the original that cover Imagination, Stereotyped Behaviors/Restricted Interests, and Other Abnormal Behaviors. There were 9 variables originally in these sections, and these were reduced to 6 variables by the autoencoders. The variables in these sections are Imagination/Creativity (IMGCR), Unusual Sensory Interest In Play Material/Person (USENS), Hand and Finger and Other Complex Mannerisms (OMAN), Self-Injurious Behavior (SELFINJ), Excessive Interest in or References to Unusual or Highly Specific Topics or Objects or Repetitive Behaviors (TOPIC), Compulsions or Rituals (RITL), Overactivity/Agitation

(ATIVE), Tantrums/Aggression (AGG), and Anxiety (ANXTY). The diagrams below shows the weights of the reduced diagnostic of this section.

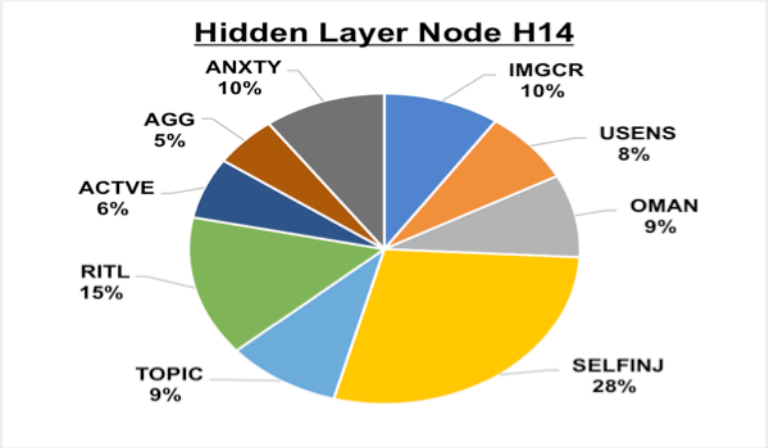

Figure 107. Relative Weights Impacts Node H14 – Module 4

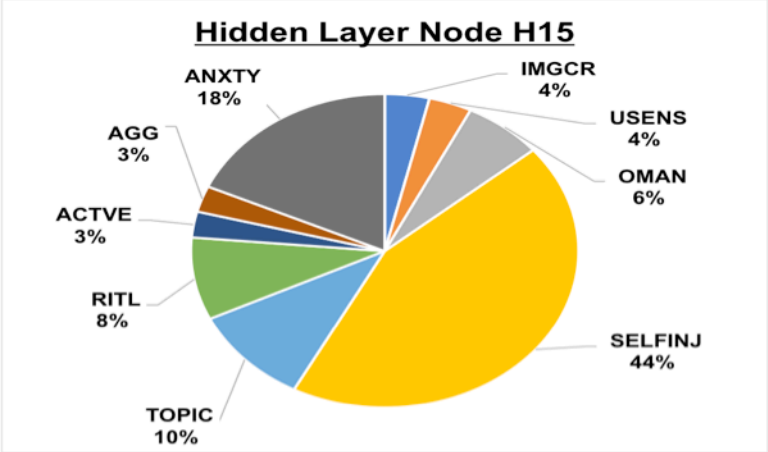

Figure 108. Relative Weights Impacts Node H15 – Module 4

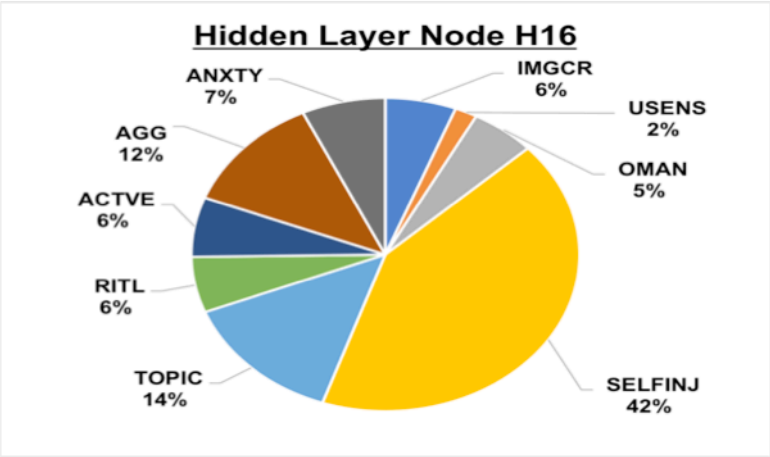

Figure 109. Relative Weights Impacts Node H16 – Module 4

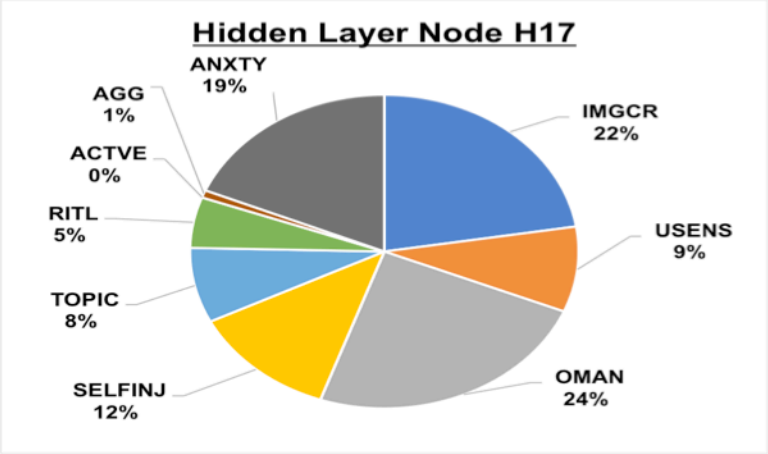

Figure 110. Relative Weights Impacts Node H17 – Module 4

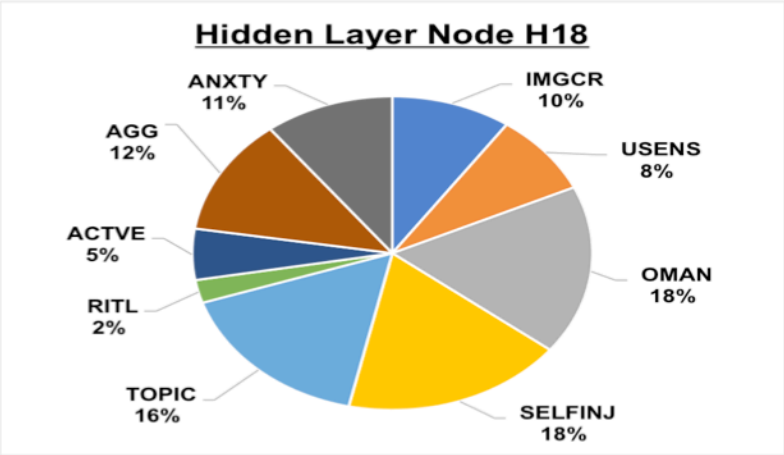

Figure 111. Relative Weights Impacts Node H18 – Module 4

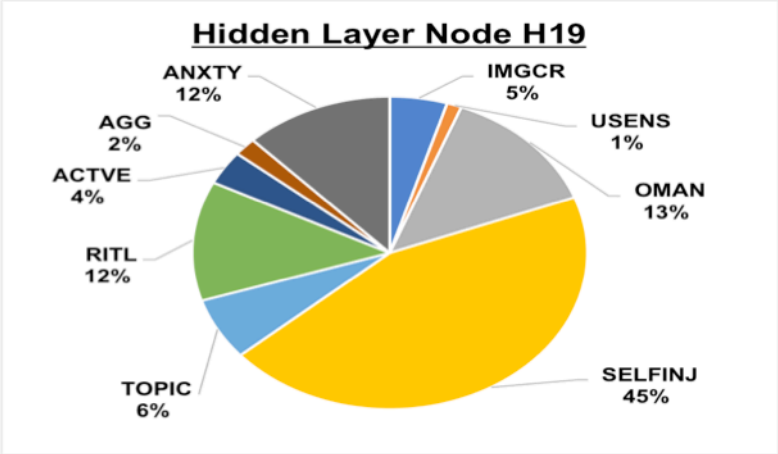

Figure 112. Relative Weights Impacts Node H19 – Module 4

The weights for this section were unusually balanced, and no variables were completely dropped. The nodes in this section were shared between input variables far more than many other sections of other modules. Interestingly enough, SELFINJ and ANXTY were the two variables with the highest strength of weights. SELFINJ in particular had cumulative weights that were more than

double the next most impactful variable. OMAN had weight strength almost equivalent to ANXTY, followed by TOPIC and IMGCR.

7.6.3.1 Correlation Between Variables

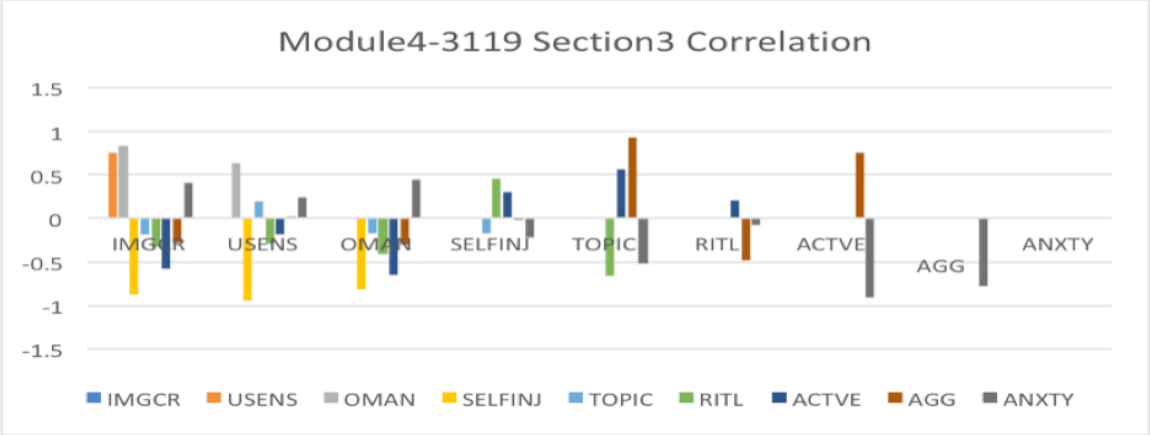

Figure 113. Weights Correlations – Module 4 Section 3

IMGCE and OMAN had a strong positive correlational relationship. (ACTIVE) and AGG also correlated strongly in the positive direction.

7.7 Insights Across Module 1 Architectures

7.7.1 Module 1 Section 1 Insights

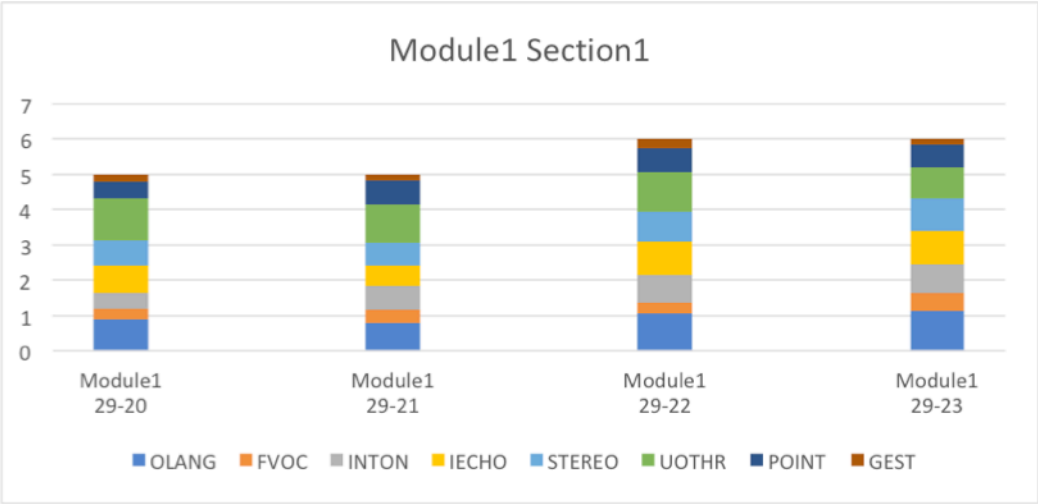

Figure 114. Module 1 Section 1 Insights

GEST was the least important variable across the board. None of its weights were negligible, but it was nonetheless the lowest ranked in terms of absolute value weights across the board. FVOC had the second lowest absolute value weights across the board, and displayed a greater degree of weight variance than GEST.

UOTHER was ranked highest in absolute value weights in three of the four autoencoders, representing the lowest dimensional reductions. OLANG was ranked second in absolute value weights in three lowest dimensional reductions, and was ranked first in the other.

7.7.2 Module 1 Section 2 Insights

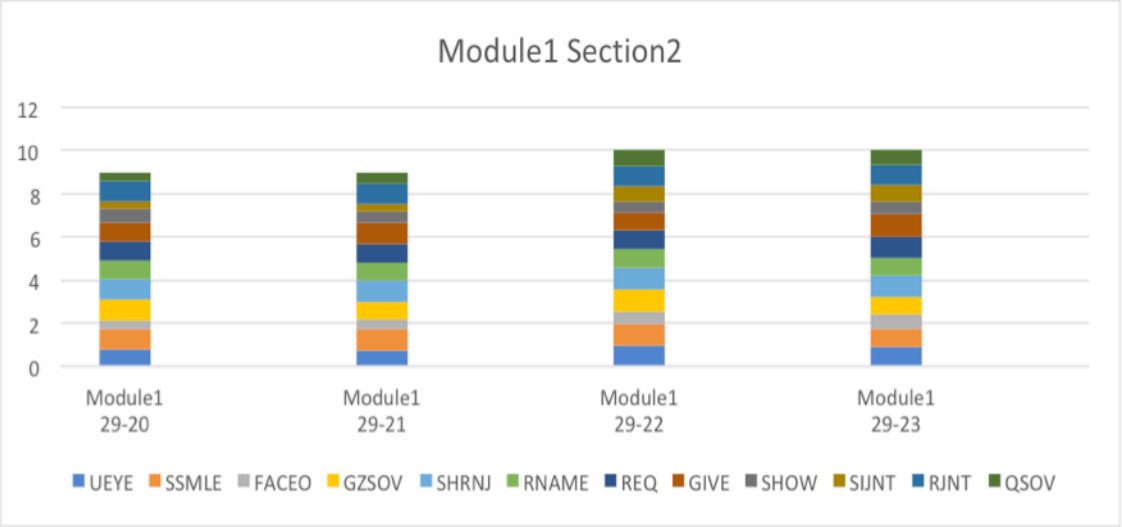

Figure 115. Module 1 Section 2 Insights

The different architectures in Section 2 of Module 1 differed to a far greater degree than in many other sections. It seems that different autoencoders converged upon radically different minima. GIVE and “GZSOV” had high absolute value weights across the board.

Interestingly enough, the 29-20 architecture showed a greater degree of similarity with the 29-22 architecture. A similar trend was seen between the 29-21 and 29-23 architectures.

7.7.3 Module 1 Section 3 Insights

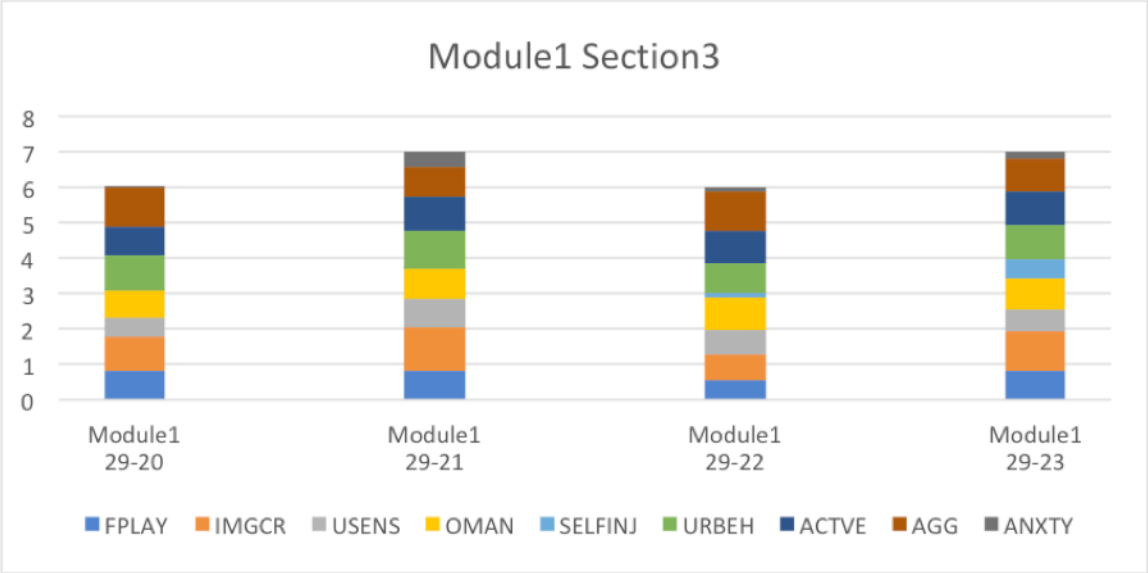

Figure 116. Module 1 Section 3 Insights

SELFINJ and ANXTY were consistently the least impactful architectures. The more significant the dimensionality reduction of an autoencoder architecture, the higher the extent to which these two variables dropped. In the lowest dimension architecture, these two variables almost wholly dropped.

AGG was the most impactful variable in the 20-variable reduced diagnostic and the 22-variable compressed diagnostic architectures. IMGCR was the most impactful variable in the other two architectures.

7.8 Insights Across Module 2 Architectures

7.8.1 Module 2 Section 1 Insights

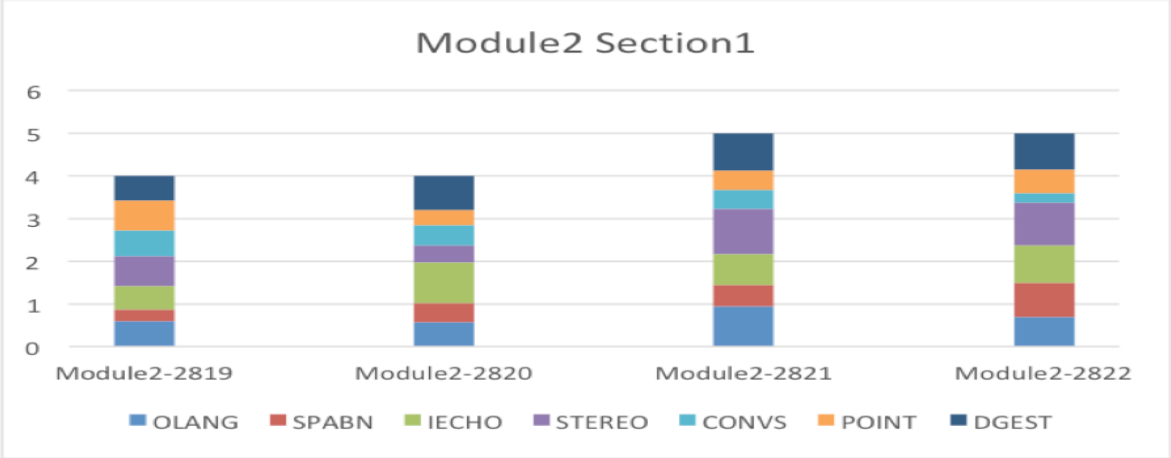

Figure 117. Module 2 Section 1 Insights

There were very few consistent trends between architectures in Module 2 Section 1. Different autoencoders found different combinations of weights to reduce dimensionality successfully.

7.8.2 Module 2 Section 2 Insights

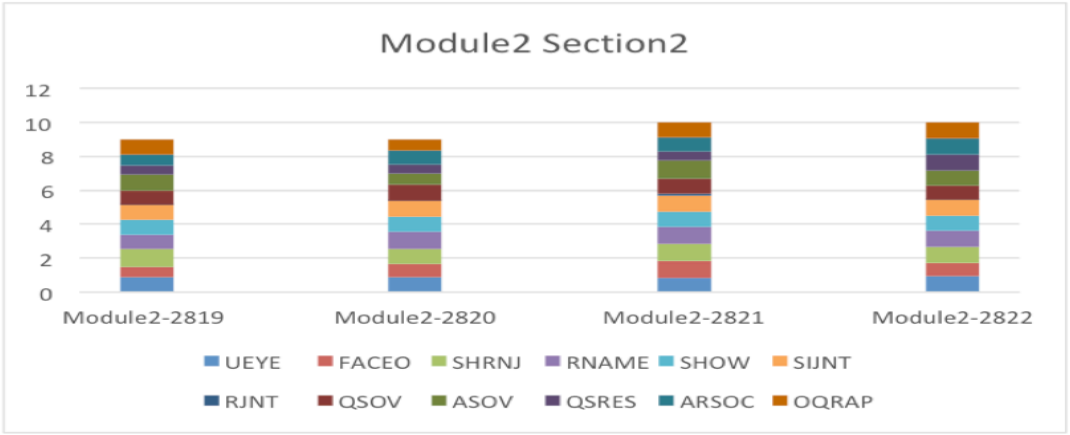

Figure 118. Module 2 Section 2 Insights

RJNT had the lowest absolute value weights across all autoencoder architectures.

7.8.3 Module 2 Section 3 Insights

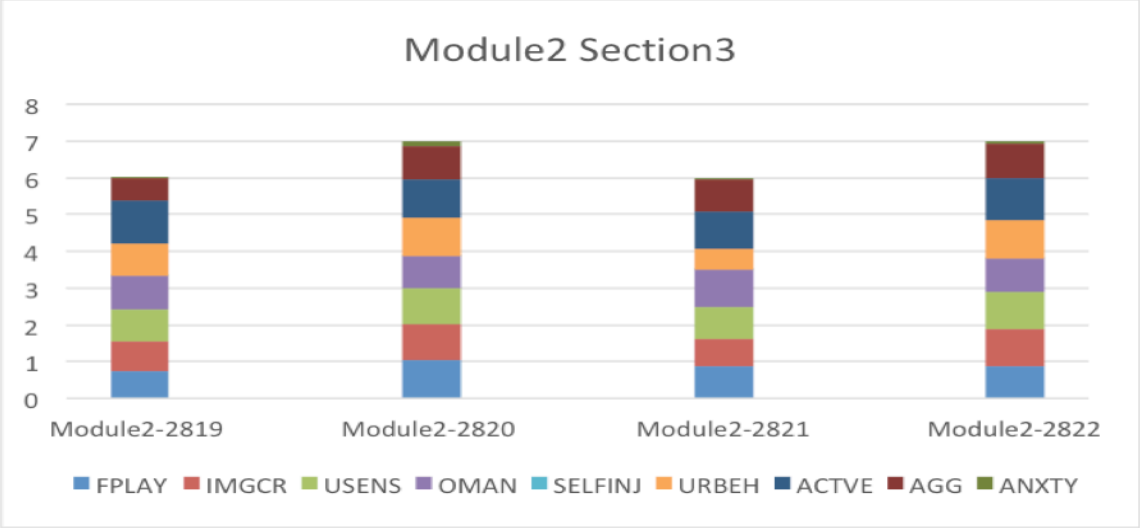

Figure 119. Module 2 Section 3 Insights

Once again, ANXTY and SELFINJ were the least represented variables in all architectures of autoencoder. ACTIVE had a strong weight presence throughout all reduced diagnostics.

7.9 Insights Across Module 3 Architectures

7.9.1 Module 3 Section 1 Insights

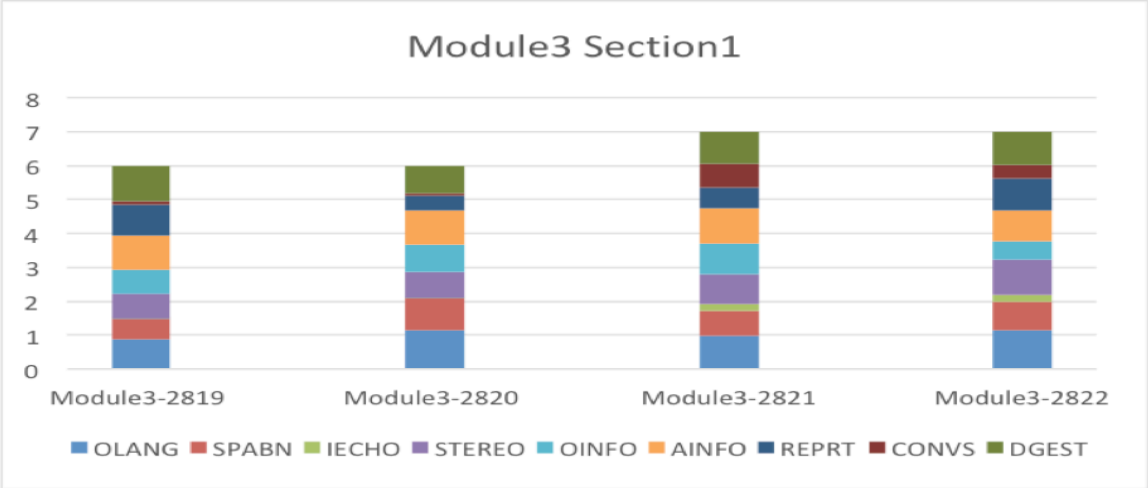

Figure 120. Module 3 Section 1 Insights

IECHO had the lowest absolute value weights in all reduced diagnostics. The absolute value of its weights was significantly smaller in the more moderate dimension reduced diagnostics (19 and 20 variables) than in the larger ones (21 and 22 variables). CONVS had consistently low absolute value weights and was the second lowest in 3 out of 4 autoencoders.

7.8.2 Module 3 Section 2 Insights

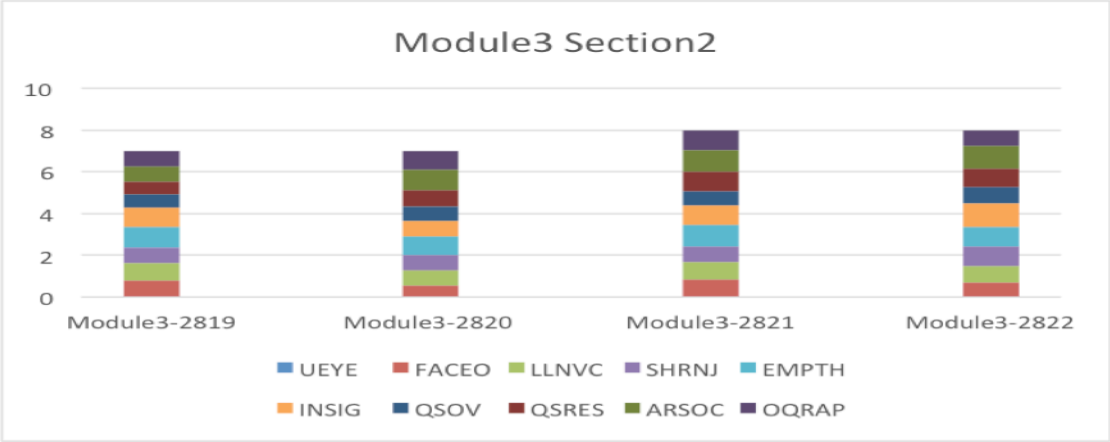

Figure 121. Module 3 Section 2 Insights

UEYE had the lowest absolute value weights across the board in all reduced diagnostics.

7.8.3 Module 3 Section 3 Insights

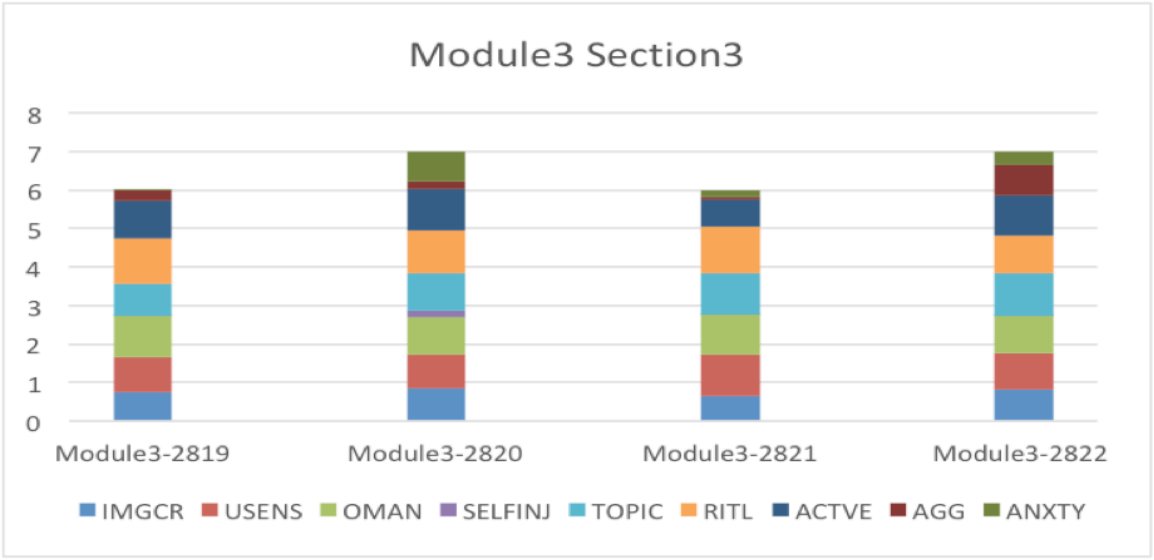

Figure 122. Module 3 Section 3 Insights

SELFINJ once again had the lowest absolute value weights in all architectures.

7.10 Insights Across Module 4 Architectures

7.10.1 Module 4 Section 1 Insights

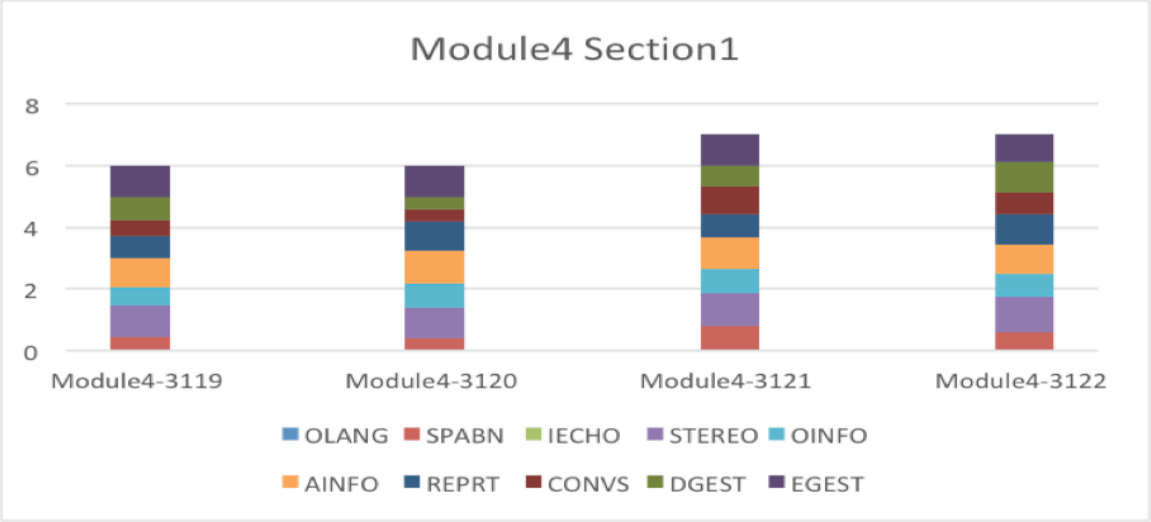

Figure 123. Module 4 Section 1 Insights

OLANG had the lowest absolute value weights in all architectures and negligible absolute value weights in all structures. IECHO had the second most moderate absolute value weights and was also insignificant in all constructions. STEREO had a strong presence in all architectures and had the most substantial absolute value weights in 3 out of 4 reduced diagnostics.

7.10.2 Module 4 Section 2 Insights

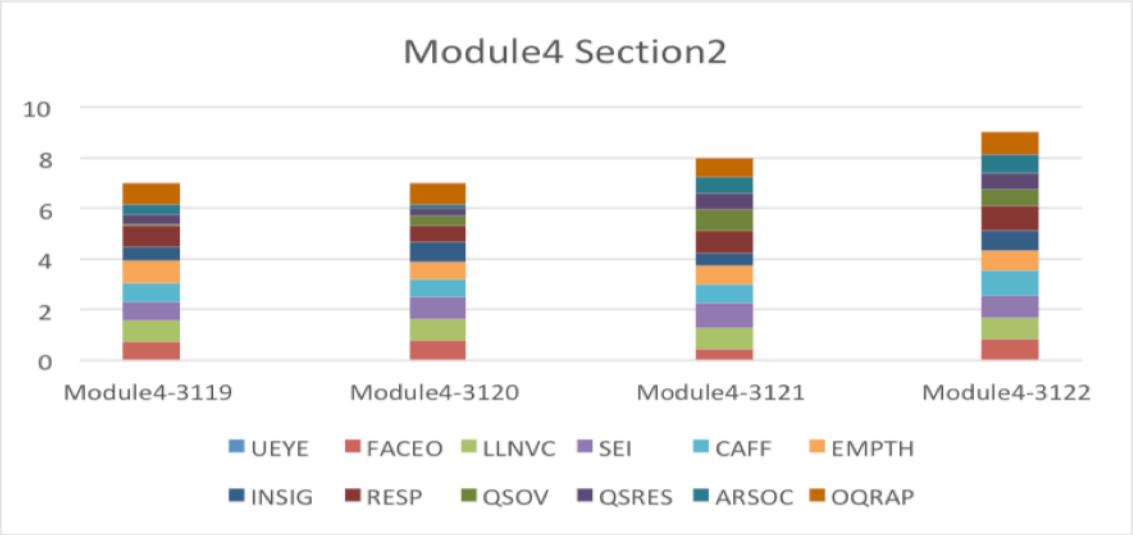

Figure 124. Module 4 Section 2 Insights

UEYE had the lowest absolute value weights in all architectures and negligibly represented.

7.10.3 Module 4 Section 3 Insights

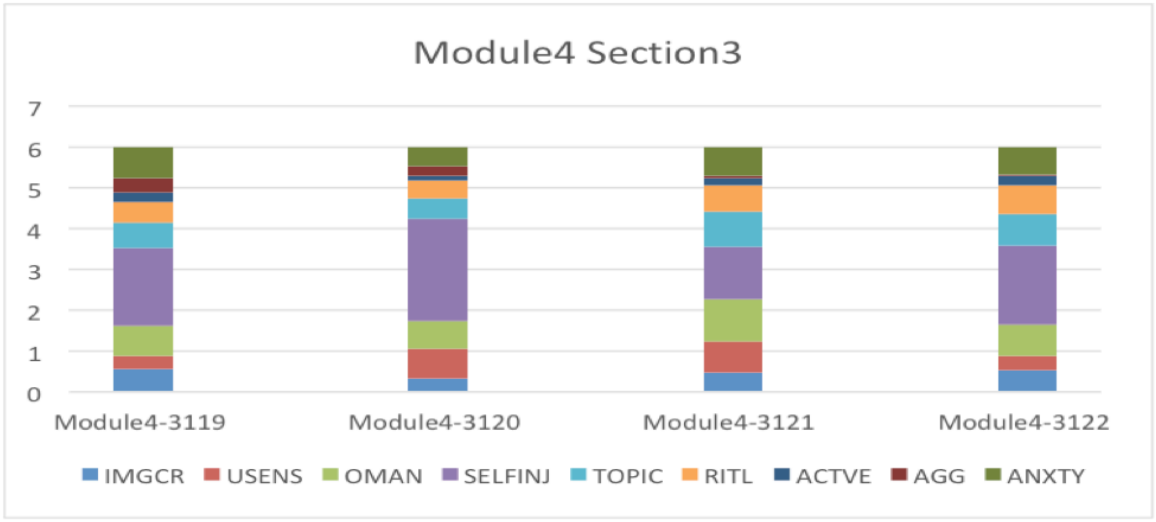

Figure 125. Module 4 Section 3 Insights

SELFINJ had by far the highest absolute value weights for all architectures in this section.

7.11 Insights Across Modules

7.11.1 Modules 1, 2 and 3

In the Modules 1, 2, and 3, SELFINJ was the lowest ranked variable across the board in its section. Its absolute value weights were negligible, and it effectively eliminated from most reduced diagnostics. In Module 4 however, it had the highest presence by a massive amount.

A study published after the date of most patient data used for this project indicated that self-injury is not a symptom of autism [44]. The fact that autoencoders repeatedly converged on solutions that eliminated self-injury might not be a coincidence. For that reason, it might be worth examining if self-injury is a reliable indicator of autism for adolescents and adults capable of having a functional conversation with an interviewer. The nature of Modules 1-3 differs significantly from Modules 4, and it is possible that self-injury's relationship with autism is somewhat nuanced, in that it is not a predictor for autism in earlier stages of social development, but is a definite symptom for autism in later stages of social development.

7.11.2 Modules 1 and 2

ANXTY had low absolute value weights consistently in Modules 1 and 2.

7.11.3 Modules 3 and 4

IECHO had low absolute values and efficiently eliminated from diagnostics in both Modules 3 and 4. UEYE also had consistently low absolute value weights.

7.12 Relative Significant of ADOS Observation Items

7.12.1 Normalization with Feature-Scaling

To provide additional context for comparing the relative strengths of weights, weight amounts were also feature scaled to fit a range between 0 and 1. The formula for feature scaling for a given section of weights looks like this.

$$\frac{X_i - X_{min}}{X_{max} - X_{min}}$$

The smallest absolute value weight for a section is set to 0 under this formula, and the largest is set to 1. All others are placed on a relative scale between 0 and 1. Normalized plots of weight values allows for one to conveniently observe the degree of separation between the strengths of different weights.

7.12.2 Module 1

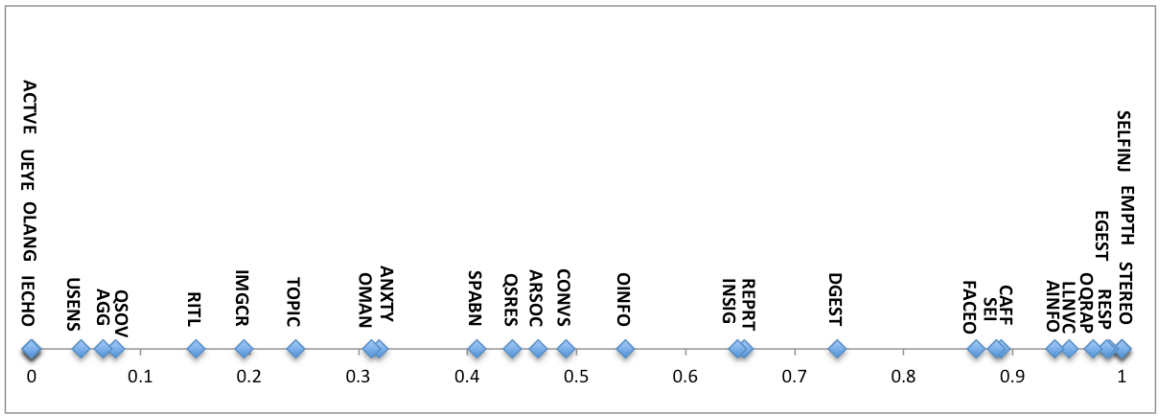

Figure 141. One-dimensional Scatter Plot - Module 4

CHAPTER EIGHT

CONCLUSION

8.1 Conclusion

Following the training of each iteration of all autoencoder architectures on all ADOS modules, a number of clear insights were provided by examining the absolute value of each variable's weights for the encoder section of each model. The effectiveness of all autoencoders was validated by their accuracy at reconstructing their input. As expected, the accuracy of a reconstruction directly correlated with the dimensionality of a hidden layer. By comparing the cumulative absolute value weights of variables, it was possible to rank the extent to which each variable impacted its relevant section in the reduced diagnostic. "Self-Injurious Behavior" was consistently eliminated in all autoencoder architectures in Modules 1-3, which suggests that a reduced diagnostic could avoid including observations for this behavior in Modules 1-3 (which differ greatly from Module 4 in their administration). This trend starkly reversed in Module 4, which relevant autoencoders consistently treated "Self-Injurious Behavior" as the highest priority when reducing the diagnostic. "Anxiety" was consistently deprioritized in Module 1 and Module 2, suggesting that it might be not be necessary to monitor for this symptom when evaluating examinees with less developed language fluency and communication abilities. "Immediate echolalia" was eliminated from Module 3 and

Module 4, suggesting that this symptom might not be necessary to include in examinations of individuals with more advanced language fluency and communication abilities.

8.2 Discussion of Context

This thesis attempted to use the weights of autoencoders to assess which variables in the Autism Diagnostic Observation Schedule would be integral to a shorter version of the diagnostic. Analyzing the weights of these autoencoders did allow for insights to be drawn regarding the extent to which variables represented in the reduced diagnostic. As such, the variables the autoencoders chose to prioritize can be treated as suggestions for focal points of a reduced diagnostic.

The fact that the autoencoders were able to reconstruct the diagnostic with a reasonable degree of accuracy suggests that machine learning approaches might be valuable in using the smaller amount of information in a shorter diagnostic to create a more extensive, more comprehensive patient profile. With sufficiently advanced machine learning approaches trained on enough large datasets, it might be possible that many types of shorter observation schedules could be used to create more significant patient profiles. This experiment suggests that machine learning approaches can enable the possibility of shorter autism diagnostics through their inferential capabilities.

It is worth discussing if the concepts that autoencoders' chose represent the foundation of a functional reduced diagnostic. There is, unfortunately, no way to currently confirming this. The possibility is worth considering though. The fact that the autoencoder reliably removed "Self-Injurious Behavior" from the diagnostic for the first three modules suggests that this might be a possibility. According to study, self-injury is no longer considered a symptom of autism[44]. The fact that every autoencoder trained on the first three modules repeatedly and reliably converged upon the solution of eliminating self-injury from the diagnostic suggests that it can isolate the variables that are most important to the diagnostic from the perspective of autism psychology.

Autoencoders might be valuable as tools to identify areas of further research within fields of psychology. If autoencoders consistently remove the same variable from a data set, it might be worth examining if that variable represents a concept that is related to the domain. In the case of these autoencoders, self-injury was repeatedly removed, and it turns out that there is experimental evidence to suggest that self-injury is not a symptom of autism. Similarly, if autoencoders regularly prioritize specific variables, that might indicate that those variables are a more integral aspect of autism than realized. Alone, these trends are entirely insufficient evidence, which is why further psychology research and experimentation would be needed.

In the big picture, psychological data contains a degree of inherent unreliability. Observation diagnoses are somewhat unreliable by nature, given

the degree of subjectivity included within them. This, unfortunately, limits the extent to which machine learning algorithms applied to psychology data can yield valuable insights about the underlying domain.

Nonetheless, this thesis indicates that machine learning algorithms applied to psychology data can potentially uncover trends that accurately portray facts about human psychology. As more powerful models are applied to more massive data sets, it is possible that machine learning algorithms can act as a bulwark against the unreliability of psychology data by identifying consistent and essential patterns that separate useful variables from misleading variables. By reducing patient profiles to critical components, autoencoders certainly have potential in this regard, especially when it comes to the domain of the Autism Diagnostic Observation Schedule.

8.3 Future Work

It would be valuable to test if autoencoders trained on a different and larger samples of ADOS data converged upon the same solutions by prioritizing and deprioritizing the same variables. Furthermore, researchers in the field of psychology might evaluate if a shorter diagnostic process can be created by designing a series of observation activities that focus on the concepts prioritized by the autoencoders in this thesis.

The fact that self-injury was, in contrast to Modules 1-3, heavily prioritized in Module 4 suggests that further research into the relationship between self-harm tendencies and adult autism might be valuable. Since the autoencoder correctly removed self-injury in Modules 1-3, a degree of credibility lent to its suggestion regarding self-injury in Module 4.

Similarly, the autoencoder also strongly highlights “Anxiety” as a target for removal in Module 1 and Module 2, and highlights “Immediate Echolalia” as a target for removal from Module 3 and Module 4. This represents another potential research area for psychologists, as it can be examined if anxiety is really a symptom of autism for individuals with underdeveloped communication abilities, and if immediate echolalia is really a symptom of autism for individuals with more developed communication abilities.

APPENDIX A

ADOS DATA APPROVAL

From: mgillesp@csusb.edu
Subject: IRB-FY2017-145 - Initial: IRB Expedited Review Approval Letter
Date: May 16, 2017 at 11:00 AM
To: 005070711@coyote.csusb.edu, kvoigt@csusb.edu

May 16, 2017

CSUSB INSTITUTIONAL REVIEW BOARD
Expedited Review
IRB# FY2017-145
Status: Approved

Ms. Sara Daghustani and Prof. Kerstin Voigt
School of Computer Science
California State University, San Bernardino
5500 University Parkway
San Bernardino, California 92407

Dear Ms. Daghustani and Prof. Voigt:

Your application to use human subjects, titled, "FINDING PREDICTIVE VALUE USING MACHINE LEARNING FOR THE AUTISM DIAGNOSTIC OBSERVATION SCHEDULE," has been reviewed and approved by the Institutional Review Board (IRB). The informed consent document you submitted is the official version for your study and cannot be changed without prior IRB approval. A change in your informed consent (no matter how minor the change) requires resubmission of your protocol as amended using the IRB Cayuse system protocol change form. **Your application is approved for one year from May 16, 2017 through May 15, 2018. Please note the Cayuse IRB system will notify you when your protocol is up for renewal and ensure you file it before your protocol study end date.**

Your responsibilities as the researcher/investigator reporting to the IRB Committee include the following 4 requirements as mandated by the Code of Federal Regulations 45 CFR 46 listed below. Please note that the protocol change form and renewal form are located on the IRB website under the forms menu. Failure to notify the IRB of the above may result in disciplinary action. You are required to keep copies of the informed consent forms and data for at least three years. Please notify the IRB Research Compliance Officer for any of the following:

1) Submit a protocol change form if any changes (no matter how minor) are proposed in your research protocol for review and approval of the IRB before implemented in your research,
2) If any unanticipated/adverse events are experienced by subjects during your research,
3) To apply for renewal and continuing review of your protocol one month prior to the protocols end date,
4) When your project has ended by emailing the IRB Research Compliance Officer.

The CSUSB IRB has not evaluated your proposal for scientific merit, except to weigh the risk to the human participants and the aspects of the proposal related to potential risk and benefit. This approval notice does not replace any departmental or additional approvals which may be required. If you have any questions regarding the IRB decision, please contact Michael Gillespie, the IRB Compliance Officer. Mr. Michael Gillespie can be reached by phone at (909) 537-7588, by fax at (909) 537-7028, or by email at mgillesp@csusb.edu. Please include your application approval identification number (listed at the top) in all correspondence.

Best of luck with your research.

Sincerely,

Caroline Vickers

Caroline Vickers, Ph.D., IRB Chair
CSUSB Institutional Review Board
